In the filament, the terminal regions are located at the innermost radius of a cylindrical structure, while the central region is exposed to the outside. It should be noticed that the filament is extremely stable; it does not depolymerize in water, in contrast to actin filaments or tubulin filaments which depolymerize in the absence of salts.

The description of the flagellin molecule is not applicable to that found in archaea. Archaeal flagella seem to have a system totally different from bacterial flagella in several aspects; (1) archaeal flagellins have signal sequences; (2) there is no channel in the filament; and (3) the filament structure resembles that of the type IV pilus.

Flagellin can be posttranslationally modified. *Salmonella* flagellin is methylated at several Lys residues by a methylase encoded by the *fliB* gene neighboring the *fliC* gene. The role of methylation of flagellin is not clear, because *fliB* mutants behave like the wild-type under ordinary conditions. *Pseudomonas syringae* flagellin is glycosylated at six Ser residues. Deglycosylation of the flagellin results in the loss of virulence to the host plant rice. Two types of flagellins of *Pseudomonas aeruginosa* are also glycosylated, but the meaning of modification is not clear. Archaeal (*Methanococcus voltae*) flagellins are highly glycosylated, which is important for flagellar assembly.

Cap Protein

Flagella have been regarded as a self-assembly systems. Indeed, flagellin can polymerize into flagella under conditions that commonly promote protein crystallization in vitro. However, in vivo, flagellin assembly requires another protein, without which the flagellin is secreted into the medium as monomers. The protein that helps filament formation is located at the tip and is thus called the cap protein or HAP2 or FliD.

The three-dimensional structure of the cap has been solved at the atomic level. The cap proteins assemble in a pentamer, forming a star-shaped structure. The star hands fit in the grooves of flagellin subunits at the tip of flagellum, leaving a small gap for a nascent flagellin to insert.

Hook

Shape

The hook, as the name suggests, is more sharply curved (almost right-angled) than the filament and is much shorter. The curvature indicates the flexibility of the hook, though it has to be stiff enough to transmit torque generated at the basal structure to the filament. From these physical properties, the hook has been regarded as a universal flexible joint. The physical property of the hook is important in understanding the behavior of the tethered cells (see “Function” section).

The length of the hook is 55 nm with a standard deviation of 6 nm, which is rather well controlled at a constant size when compared with the length of filament. However, this large standard deviation, 10% of the mean, indicates that the hook length control is not deterministic but probabilistic. Polyhook is a mutant hook of indefinite length, obtained in *fliK* mutants. There are several factors that affect hook length: FliK, the hook protein FlgE, the hook cap protein FlgD, and C-ring components (FliG, FliM, and FliN). Among them, FliK is a major factor for hook length control, because hook length in various species is proportional to the molecular length of the corresponding FliK (see section “Morphological Pathway”).

It is not clear whether the polyhook is a tandem polymer of the wild-type hook. Its shape is a right-handed superhelix. The wild type hook has the same superhelix but consists of about one-fourth of the helical pitch, which is 55 nm.

Hook protein

The hook is a tubular polymer made of a single kind of protein: hook protein or FlgE. The molecular size of hook protein varies from 264 amino acids (*Bacillus subtilis*) to 718 amino acids (*H. pylori*), but is around 400 amino acids for most species.

The architecture of hook protein resembles that of flagellin: the amino acid sequence in both terminal regions is well conserved, but in the central region it is variable. Hook protein folding also completes on assembly. The three-dimensional structure of the hook protein in the hook has been solved at the atomic level.

The amino acid sequences of the terminal regions of FlgE is homologous with that of FlgG, or the distal rod (see “Rod” section). There is an extra sequence of 18 amino acids in the N-terminal region of FlgG. Insertion of the amino acid fragment into FlgE causes the change of hook curved shape into straight shape. Consequently, the physical properties of the hook change; it is not flexible anymore but stiff so that flagellar function as a propeller is deteriorated.

Spirochete flagella are confined in the periplasmic space and are called periplasmic flagella. There must be enormous friction between the periplasmic flagella and membranes when the flagella rotate. Although the hook looks ordinarily curved, the architecture is quite different from that of any other hooks. The hook protein subunits are covalently cross-linked to each other in a self-catalyzing manner, resulting in unusually stable hooks.

Scaffolding Protein FlgD

The hook does not self-assemble *in vivo*; it requires a helper protein, FlgD, which functions in a similar way as FliD does for filament formation. FlgD sits at the tip of the nascent hook to polymerize hook protein coming out from the central channel. When the hook length reaches around 55 nm, FlgD is replaced by HAP1 (FlgK), which remains in the mature flagellum. Because of its temporary existence, FlgD is regarded as a scaffolding protein.

Hook-associated proteins

There are two minor proteins between the hook and filament. They are called hook-associated proteins (HAPs), because they were found at the tip of the hook in several filament-less mutants. Originally, there were thought to be three HAPs, called HAP1–3 in the order of their molecular size. HAP2 (FliD) turned out to be located at the tip of the filament as described above, leaving HAP1 (FlgK) and HAP3 (FlgL) between the hook and filament. They are, therefore, hook–filament junction proteins.

The number of subunits of HAP1 and HAP3 in a filament are estimated to be five or six, indicating that they form one-layer rings sitting one on another. The roles of these two HAPs have been ambiguous. The idea of a connector to smooth the junction between the two polymers is blurred by the question, ‘why are not one but two kinds necessary.’ In a mutant of HAP3, filaments undergo polymorphic transitions so easily that cells cannot swim smoothly, suggesting a specific role of HAP3 as a stabilizer of filament structure.

Basal Structure

Flagella are anchored in the cell wall. The structural entity for the anchoring was originally called the basal structure or basal granule, hinted at by vague images by electron microscopy. Since DePamphilis and Adler in 1974 defined the details of the basal structure, it has been called the basal body. The basal body typically consists of four rings and one rod in Gram-negatives.

The basal body, when isolated from the cell body, contains some stable components necessary for flagellar function, but fragile and soluble components were detached from the basal body during purification. In 1985, one such fragile structure was found attached to basal bodies purified by a modified method; it was named as the cytoplasmic ring (C ring). In 1990, another rod-like structure was found in the center of the C ring and named as the C rod. In 2006, flagellar export ATPase (FliI) was found at the periphery of the C ring as a complex with the supporter protein FliH. In 2011, the electron cryomicroscopy revealed that those soluble proteins actually form a dome-like structure beneath the C ring. Therefore, the *in situ* basal structure is a gigantic structure consisting of the basal body, the C ring, the C rod, export ATPase, and a few accessory proteins.

Basal body

The basal body contains rings and a rod penetrating through them. The number of rings varies depending on the membrane systems: four rings in most of Gram-negatives and two rings in Gram-positives exemplified by *B. subtilis*. Some variations in the number (such as five rings in *C. crescentus*) have been occasionally seen. The fifth ring might be a ghost image of electron microscopy or could be erroneously added during ring formation (see “Rod” section).

The structure of the basal body of *S. typhimurium* has been extensively analyzed. The physical and biochemical properties of the substructures of the basal body described below are from *S. typhimurium*, unless otherwise stated.

MS-ring complex

Earlier studies on flagellar motor function assumed that torque would be generated between the M and S rings, which face each other on the inner membrane. However in 1990, it was shown that a single kind of protein, FliF, self-assembles into a complex consisting of the M and S rings and a part of the rod. FliF is 65 kDa, the largest of the flagellar proteins. It contains no cysteine

residues. Overproduction of FliF in *Escherichia coli* gives rise to numerous MS-ring complexes packed in the inner membrane, indicating that the central channel is physically closed. Image analysis revealed that the MS-ring complex is composed of 24–26 subunits of FliF.

The S ring has been seen in the basal bodies from all the species studied so far (>30 examples). It stays just above the inner membrane and has no apparent interaction with any other structures, thus named S (supramembrane) ring. Besides, it is very thin and the role of the S ring remains mysterious.

Although the MS-ring complex is no longer regarded as the functional center of the flagellar motor, it is still the structural center of the basal structure and, as will be seen later (see “Genetics” section), plays an important role in flagellar assembly.

Rod

The rod is not as simple as its name suggests; it is structurally separated into two parts: the proximal rod and the distal rod of 10 nm length each. The proximal rod consists of four proteins (FliE, FlgB, FlgC, and FlgF), while the distal rod consists of only one kind of protein FlgG. Filaments, when sheared off from the cell body by external physical force, often retain the hooks and the distal rods at the proximal ends, indicating that the rod breaks at the midpoint between FlgF and FlgG.

Rod formation seems complicated because of the five component proteins. No intermediate rod structure has been observed; either there is a whole rod or no rod at all. Two *flgG* point (G65V, G183R) mutants produce distal rods ca. 60 nm long. Double mutants of a *flgG* point (G65 V) mutation and *fliK* deletion give rise to polyrods, rods of undefined length, indicating that FliK controls the polyrod length by the same mechanism for the hook-length control. In 2017, it was shown that intrinsic rod-length is limited by the width of the periplasmic space as short as 10 nm, indicating that the physical barrier of the outer membrane stops further elongation of the rod.

Since many P rings can be formed on the long distal rod, FlgG is the target for interaction with FlgI, the subunit of the P ring (see below).

LP-ring complex

The outermost ring, the L ring, interacts with the lipopolysaccharide layer of the outer membrane, and the P ring just beneath the L ring may bind to the peptidoglycan layer. The LP-ring complex works as a bushing, fixed firmly enough to hold the entire flagellar structure stably in the cell surface.

The component proteins, FlgH for the L ring and FlgI for the P ring, have signal peptides, indicating that they are secreted through the general secretory pathway (GSP), which is the exception for flagellar proteins as will be seen later (see “Genetics” section). FlgH undergoes lipoyl modification.

P ring formation precedes L ring formation; without the P ring, L ring formation does not occur. Once the L and P rings have bound together to form the LP-ring complex by an unknown mechanism, this complex is extraordinarily resistant against extremes of pH or temperature. Treatments with pH 11, pH 2, or boiling for a minute do not destroy the complex, confirming that the complex serves as a rigid bushing in the outer membrane. However, essential roles of the complex are still ambiguous because no corresponding structure has been found in Gram-positive bacteria and spirochaetes.

C ring

The C ring is missing from the basal structure when biochemically isolated. It is resistant to the nonionic detergent Triton X-100 but is destroyed by the alkaline pH or high concentration of salts employed by the conventional purification method. The shape of the C ring is easily flattened on a grid during preparation for electron microscopy. By electron cryomicroscopy, the C ring shows a cup shape, whose structure is solved at 2-nm resolution.

Genetic studies revealed that the C ring plays important roles in chemotaxis, torque generation, and flagellar formation. The C ring consists of the switch proteins (FliG, FliM, and FliN) necessary for changing the rotational direction of the motor, and so is called the switch complex. FliG directly binds to the cytoplasmic surface of the M ring. FliM binds to FliG, and FliN to FliM. Stoichiometry of these molecules in the C ring is determined from the high-resolution image of the C ring: 24–26 copies of FliG, 32–36 copies of FliM and FliN. The copy number of FliN can be increased up to 100 without affecting the motor function. FliM in the C ring directly binds signal molecules, CheY, produced in the sensory transduction system, but the mechanism of the switching is still ambiguous.

The role of the C ring in flagellar formation is clear in deletion mutants of one of the three genes; the mutant cells are non-flagellated. Point mutations in one of these genes result in short hooks, indicating the C ring is involved in regulation of secretion of at least hook proteins (see “Hook” section).

Export apparatus

Flagella have been regarded as a self-assembly system, similar to that of bacteriophage. However, flagellar assembly is quite different from phage assembly in many ways. First, the flagellum, being an extracellular structure, assembles not in the cytoplasm but outside the cell. Second, the component proteins have to be transported from the cytoplasm to the outside. Third, assembly proceeds in a one-by-one manner at the distal end of the nascent structure.

For this kind of assembly, a protein secretion system must play an important role in an ordered secretion consistent with cell growth and cell division. As a matter of fact, among 14 genes required in the very first step of flagellar assembly, more than half of

the gene products are necessary to form a protein complex called an export (or secretion) apparatus. One of them, FliI, has an ATPase activity, suggesting that one step in the export process requires ATP hydrolysis as an energy source. However, transport of substrates through the channel in the axial structures (the rod, hook, and filament) of the flagellum utilizes PMF as energy source. Thus, FliI may be used at the first step of the process, that is, insertion of substrates into the secretion gate. However, flagellin, the most abundant substrate, does not use FliI for secretion.

The physical body of the secretion gate has not been identified yet; the C rod is a strong candidate, judging from its location at the center of the C ring. Genetic analysis indicates that at least five components are required for the C rod: FliP, FliQ, FliR, FlhA, and FlhB, all of which have membrane-spanning region(s). How these component proteins are inserted in the small space of the central area of the MS-ring complex is still mysterious (see “Morphological Pathway” section).

Function

The function of flagella is described here briefly so that the meaning of structure can be understood. Bacterial flagella rotate. There is no correlation between bacterial flagella and eukaryotic flagella either in function or in structure; the type of movement, the energy source, and the number of component proteins differ greatly between the two. No evolutionary correlation between these two types of flagella has been shown. Among motile bacterial species, swimming by flagellar rotation is the most common. However, the flagella of *Spirochetes* are an exception; flagella rotate in the periplasm and accordingly the helical cell body rotates to move in a viscous medium or glide on the surface. Several families such as *Myxococcus*, *Mycoplasma*, and *Cyanobacteria* do not have flagella but move on a solid surface by a gliding motion; *Myxococcus* moves by means of type IV pili and *Mycoplasma* has motor proteins on the cell surface as the locomotive organ.

Torque

Rotational force (torque) of the flagellar motor is difficult to measure directly but can be estimated from the rotational speed of flagella. The method most widely employed is the tethered cell method, developed by Silverman and Simon in 1974. The rotation of a cell body caused by a tethered filament can be observed with an ordinary optical microscope. Rotating flagella on a cell can be observed by dark-field microscopy, developed independently by Robert M. Macnab and Hirokazu Hotani in 1976. Using laser as the light source of a dark-field microscope, the rotational speeds of a flagellum on a cell stuck on the glass surface were measured at the time resolution of milliseconds. A more sophisticated method employs the fluorescent microscope to detect the rotation of fluorescent beads attached to the hook. Most of the experiments for measuring torque have been done by Howard C. Berg and his colleagues, followed by several Japanese groups.

Rotational direction

Flagella of many species (e.g., enterobacteria) can rotate in both the directions: clockwise (CW) and counterclockwise (CCW).

Under ordinary circumstances, around 70% of the time is occupied by CCW rotation, which causes smooth swimming. A brief period of CW rotation causes a tumbling motion of the cell. There is no perceptible pause in switching between the two modes.

In some bacterial species such as *Rhodobacter sphaeroides*, a lateral flagellum on a cell rotates in the CW direction only with occasional pauses. During pauses, the filament takes on a Coiled form and curls up near the cell surface. Upon application of torque on this filament, the Coiled form extends to a semistable, right-handed form that closely resembles a Curly form. The CW rotation of this right-handed helix causes a forward propulsive force on the cell.

Rotational speed

Flagella on a stuck cell (the cell body attaches to the glass surface but flagella freely rotate) rotate at ca. 200 Hz, which is comparable with that of a free-swimming cell. In contrast, tethered cells (one flagellum attaches to the glass surface but the cell body freely rotates) rotate only at ca. 20 Hz. It has been long believed that the cell body is too large and thus hydrodynamically too heavy for a tiny motor to rotate faster. However in 2007, we have shown that tethered cells almost always interact with the surface; the distance between the cell and the glass surface is only 55 nm on average, which is determined by the hook length. The hook seems to play an active role as a flexible joint in the interaction.

The rotational speeds of flagella correlate directly with the torque and inversely with the viscosity of the solution. The correlation appears as a straight line in a speed–torque diagram; the higher the viscosity, the slower the speed is. This indicates that the torque of the flagellar motor is constant over a wide range of speed.

The highest speed so far measured is 1700 Hz for *V. alginolyticus*. However, only 10% of the torque derived from the speed is used as a propulsive force, the rest being lost in slippage of flagella in the medium. In general, cells with single polar flagellum swim ($>100 \mu\text{m s}^{-1}$) faster than cells with peritrichous flagella ($<20 \mu\text{m s}^{-1}$).

Energy source

The energy source of torque generation in the flagellar motor is not ATP but proton motive force (PMF). PMF is the electrochemical potential of the proton and results in the flow of protons from outside to inside the cell. PMF consists of two different forms of energy: membrane potential and entropy caused by a difference in pH between outside and inside the cell. Since these two parameters are independent and separable from each other, either one can, in principle, be abolished without affecting the other.

It is not known whether protons directly flow through the flagellar motor to generate torque or flow nearby to induce conformational changes of the component proteins in the C ring. In *V. alginolyticus*, sodium motive force (SMF) is used for the polar flagellum, whereas the lateral flagella use PMF.

One of the goals of flagellar research is the elucidation of the mechanism by which PMF or SMF is converted into torque in the motor.

Switching of rotational direction

Switching of the rotational direction of flagella is the primary basis of chemotaxis, one of the most important behaviors shown by bacteria. Damage in the switching mechanism results in a rotation biased to either CCW only or CW only. Although cells that rotate only CCW swim smoothly in liquid, they cannot form a swarm (chemotaxis) ring on a semisolid agar plate.

In a strict sense, the switching mechanism will not be solved until the mechanism of rotation is solved. However, factors involved in the mechanism are known; an effector binds to FlIM of the switch complex in the flagellar motor. The effector is the phosphorylated form of CheY, a signaling protein within the sensory transduction system.

Genetics

Flagellar genetics has been most extensively studied in *S. typhimurium*, especially using the enormous number of SJW (Salmonella Japan Waseda) strains that Shigeru Yamaguchi has collected for >30 years. Once the fundamental genetics was established, molecular biology has been serving powerful tools to reveal the details. Topics regarding the *fla* genes in this section are mostly based on results obtained from *Salmonella* strains, whereas chemotaxis (*che*) genes and motility (*mot*) genes were more extensively analyzed using mostly *E. coli* and other strains (e.g., *Rhizobium* spp., *Vibrio* spp., etc.).

Flagellar Genes

There are >50 flagellar genes divided into three types according to null mutant phenotype (Fig. 4).

The *fla* genes

Defects in the majority of the flagellar genes result in flagellar-deficient (Fla^-) mutants. These genes were originally called *fla* genes.

In 1985 when the number of genes exceeded the number of letters in the alphabet, a unified name system for both *E. coli* and *S. typhimurium* was proposed by Robert M. Macnab and introduced in the field with approval by all contemporary geneticists. They are *flg*, *flh*, *fli*, and *flj*; each for one of the clusters of genes scattered in several regions around the chromosome (Fig. 4). When a particular gene does not have the corresponding gene in *Salmonella*, historical names are used, for example, *flaF*, *flaG*, *flbS*, and *flbT*.

The *mot* genes

Mutants that produce paralyzed flagella are called motility-deficient (Mot^-) mutants. There are only two *mot* genes (*motA* and *motB*) in *S. typhimurium*. In *V. alginolyticus*, there are two sets of flagella—polar and lateral. The energy source for each motor is

Fig. 4 Genetic map of *Salmonella typhimurium*. Flagellar genes distribute in several clusters on the chromosome. Arrows over genes indicate the size of operons and their transcriptional directions. The numbers on the arrows indicate classes of transcription. The regulation of class 2 and class 3 is not simple; some operons are expressed twice in class 2 and class 3. Chemotaxis receptors (*Tsr*, *Trg*, and *Tag*) and receptor homologues (*MCP*) are scattered on the chromosome.

distinguishable; SMF for the polar flagellum and the PMF for the lateral flagella. *Mot* genes for the polar flagellum are called *pomA* and *pomB*. A certain sequence of a few amino acids in Mot proteins is responsible for selection of ions. There are four more *mot* genes (*motA*, *motB*, *motX*, and *motY*) in *V. alginolyticus*, *R. sphaeroides*, and *Aeromonas hydrophila*. *V. alginolyticus* MotX and MotY are associated with the basal body of sodium-driven polar flagellum and required for stator formation.

P. aeruginosa retains one set of *mot* genes (*motA* and *motB*) and another set (*motC* and *motD*). Although it is indicated that the *motC* and *motD* genes play an important role in pathogenicity, their roles in motor function are not known. There was renaming of some *mot* genes; MotD of *Sinorhizobium meliloti* and related alpha-proteobacteria turned out to be the flagellar-hook-length regulator FliK, indicating that original naming was wrong. MotE in *S. meliloti* is a chaperone specific for the periplasmic motility protein, MotC.

The *che* genes

Mutants that can produce functional flagella but cannot show a normal chemotactic behavior are called chemotaxis-deficient (Che^-) mutants. These are divided into two types—general chemotaxis mutants (authentic Che^-) and specific chemotaxis mutants. The former involve the proteins working in the sensory transduction (*CheA*, *CheW*, *CheY*, *CheZ*, *CheB*, and *CheR*), and the latter involve the receptor proteins for attractants such as amino acids and sugars (e.g., *Tsr*, *Tar*, *Trg*, and *Tap*).

In some species, there are multiple homologues of the *E. coli* chemotaxis genes. For example, *R. sphaeroides* possesses $5 \times \text{cheA}$, $2 \times \text{cheB}$, $3 \times \text{cheR}$, $4 \times \text{cheW}$, and $6 \times \text{cheY}$ arranged in several operons. Thirteen chemoreceptors, including both membrane-spanning and cytoplasmic or transducer-like proteins (Tlps), have been identified (as of 2017). These are differentially expressed according to the environmental conditions. It is not known whether the products of the *che* operons operate through independent, linear pathways or there is significant cross-talk between the components of these operons.

In *V. cholerae*, there are five *cheY* genes including one putative *cheY*. It was shown that only one of them directly switches flagellar rotation. In *E. coli*, *CheY* dephosphorylation by *CheZ* extinguishes the switching signal. But instead of *CheZ*, many chemotactic bacteria contain *CheC*, *CheX*, and *FliY* for dephosphorylation.

Gene Clusters in Four Regions

Most flagellar genes are found in gene clusters on the chromosome. They are in four regions: the *flg* genes in region I, the *flh* genes and *mot* and *che* genes in region II, and the *fli* genes in regions IIIa and IIIb (Fig. 4). The *flj* operon (including *fljA* and *fljB*) in region IV involves an alternative flagellin gene to *fliC* and is only found in *Salmonella*. Either FliC flagellin or FljB flagellin is produced at one time. The *hin* gene inverts the transcriptional direction at a certain statistical frequency; if the *flj* operon is being expressed, FljA represses *fliC*, allowing FljB flagellin alone to be produced. This alternate expression of two flagellin genes is called “phase variation.”

This clustering of flagellar genes is also observed in other peritrichously flagellated species; grouping of particular genes and gene order are similar to those in *S. typhimurium*. Flagellar genes for the polar flagellum in *Pseudomonas* spp. and *Vibrio* spp. form clusters in a few regions, but the gene order is different from that of peritrichous flagella. The polar flagellum requires special regulatory genes (such as *fleP*, *fleQ*, *flhF*, *flhG*) to localize one flagellum at the pole of the cell, which peritrichous flagella do not require them. Flagellar genes of some species (*C. crescentus* or *Campylobacter jejuni*) are scattered in more than seven regions; the extreme case is *H. pylori*, in which single flagellar genes, or at most three-gene clusters, are scattered all over the chromosome. It is interesting to see that a cluster, FliC (flagellin)–FliD (the capping protein)–FliS (chaperone for FliC)–FliT (chaperone for FliD), is ubiquitously found in all species but not in *H. pylori* and *Buchnera* spp. Since *H. pylori* flagellum is covered by the membranous sheath, the mechanism of flagellar assembly could be different from that of *Salmonella*. For example, *H. pylori* FlgM is not secreted but stay in the cytoplasm, and it interacts with FlhA (a component of the secretion gate).

Transcriptional Regulation

Flagellar construction requires a well-ordered expression of flagellar genes not only because there are so many genes, but also because flagellar assembly requires only one kind of component protein at a time, as described in previous sections. There is a strict hierarchy of expression among the flagellar genes. The hierarchy is controlled or maintained by a few prominent regulatory proteins.

Hierarchy: Three Classes

The hierarchy of flagellar gene expression is divided into three classes: class 1 regulates class 2 gene expression, and class 2 regulates class 3. Class 1 contains the master genes: only two genes in one operon, *flhD* and *flhC*.

Class 2 consists of 35 genes in eight operons. There are two regulatory genes, *fliA* and *flgM*; the rest are component proteins of the flagellum or the export apparatus.

Class 3 genes code flagellin, MotA and MotB, and all the Che proteins. Flagellin is one of the most abundant proteins in a cell, suggesting that the tight regulation in the hierarchy guarantees the economy of the cell.

There is another class of regulation pathway in species that produce polar flagellum. In *P. aeruginosa*, there are four classes; class 1 contains the master gene *fleQ*, class 2 contains 25 genes necessary for constructing the export apparatus, class 3 contains 12 genes necessary for completing the hook-basal body, and class 4 contains 13 genes to produce the filament and the chemotaxis system.

Master Genes, *flhDC*

Master gene products form a tetrameric complex of FlhD/FlhC, which works as a transcriptional activator of the class 2 operons.

The master operon (*flhDC*) is probably transcribed with the help of the “housekeeping” sigma factor, sigma70. The master operon is also activated by a complex of cyclic AMP and catabolite activator protein (cAMP–CAP), which binds to a site upstream of the promoter.

In *P. aeruginosa*, *fleQ* is the master gene instead of *flhCD*. However, *fliA* is out of the control of *fleQ*; the controlling element of *fliA* is not known yet.

Sigma Factor F (sigma F: FliA) and Antisigma Factor (FlgM)

The FliA and FlgM proteins expressed from the operon competitively regulate the class 3 operons. FliA is the sigma factor that enhances the expression of the class 3 operons, while FlgM is an antisigma factor against FliA.

If the hook and basal body have been constructed normally, FlgM is secreted into the medium through the basal body and the complete hook, allowing free FliA proteins to work on the class 3 operons. However, if the hook and basal body construction is somehow halted in the middle of process, FlgM stays in the cytoplasm in a complex with FliA, maintaining shut-off of the expression of the class 3 operons. FliK plays an important role in switching of the secretion modes (see “Hook Growth” section).

A combination of *fliK–fliA–flgM* genes has been found in genomes of all species so far studied except *Buchnera* spp. that lacks all of the *fla* genes necessary for filament formation.

Global Regulation Versus Internal Regulation

There are several external genes or factors that affect the flagellar gene expression through the master operon *flhDC*. Some of the factors show pleiotropic effects on many cellular events such as cell division, suggesting that flagellation would be finely tuned with the cell division cycle due to well-organized tasks of global regulation systems.

As described above, the master operon (*flhDC*) is probably transcribed using the “housekeeping” sigma factor, sigma70. In the last decades, other factors regulating or modulating *flhDC* expression have been identified, mainly in *E. coli*. The motility of *E. coli* cells is lost at temperatures higher than 40°C as a result of reduced *flhDC* expression. It has been shown that some of the heat-shock proteins are involved in both class 1 and class 2 gene expressions. This strongly suggests that flagellar genes are under global regulation in which the heat-shock proteins play a major role; probably the proper protein folding (or assembly) mediated by these chaperons is essential for flagellar construction.

Other adverse conditions such as high concentrations of salts, carbohydrates, or low-molecular-weight alcohols also suppress *flhDC* expression, resulting in lack of flagella. The regulation by all these factors is independent of the cAMP–CAP pathway.

Flagellar gene expression is also controlled by the ubiquitous bacterial second messenger cyclic diguanosine monophosphate (c-di-GMP). In response to changing environments, fluctuating levels of c-di-GMP inversely regulate flagellar formation and thus cell motility.

The factors and mechanism of directly turning on the master *flhDC* operon in accordance with the cell cycle are yet unknown. Another goal of the flagella research is the elucidation of the roles of global regulators on flagellar gene expression to uncover the complex regulatory network connecting flagellation and cell division.

Morphological Pathway

The order of the steps toward the construction of a flagellum (the morphological pathway) was analyzed in the same way as was used for bacteriophage—analyzing intermediate structures in various flagellar mutants and aligning them in size from small to large ones. Flagellar construction starts from the cytoplasm, progresses through the periplasmic space, and finally extends to the outside of the cell (Fig. 5).

In the Cytoplasm

The smallest flagellar structure recognizable by electron microscopy is the MS-ring complex. Since the MS-ring complex self-assembles from FliF protein alone in the cytoplasmic membrane, it has been regarded as the first structure in the pathway of the flagellum construction. However, it is not functional by itself but requires five other membrane proteins (FliP, FliQ, FliR, FlhA, and FlhB) to form the secretion gate for external structure of the flagellum (see “Export apparatus” section). It is not clear at the moment

Fig. 5 Morphological pathway of flagellation. Flagellar construction proceeds from *left to right*. Gene products shown above the membranes are incorporated in the flagellar structure at each step. The gene products shown under the membranes are chaperones for the component protein just above the membrane (shown in *italics*) or enzymes: FliI is an ATPase, and FliJ is muramidase.

whether the MS-ring complex comes first or a complex of the secretion-gate proteins comes first. Nevertheless, the MS-ring complex works as the construction base of the flagellum. When the C ring attaches on the cytoplasmic side of the M ring, the gigantic complex starts secreting other flagellar proteins to construct the extracellular part of the flagellum.

In the Periplasmic Space

The first extracellular structure constructed on the MS-ring complex is a rod. The proximal rod grows short but the distal rod may grow longer than 10 nm (see “Rod” section). The distal rod growth stops when it reaches the outer membrane, and then the hook starts growing. However, the outer membrane physically hampers again the hook growth until the outer-ring complex makes a hole in it. Among flagellar proteins, FlgH and FlgI, the component proteins of the outer-ring complex, are exceptional in terms of the manner of secretion; these two proteins have cleaved signal peptides and are exported through the GSP. However under special conditions, filaments can grow in the absence of the outer rings but stay in the periplasm to form the periplasmic flagella as seen in spirochaetes.

Outside the Cell

Once the physical block by the outer membrane has been removed, the hook resumes growth with the aid of FlgD until the length reaches about 55 nm. Then, FlgD is replaced by HAPs, which is followed by the filament growth. The filament growth proceeds only in the presence of FliD (HAP2 or filament cap protein); without this cap, exported flagellin molecules are lost to the medium.

Flagellar Protein Export as a Type III Secretion System

There are several ways to transport proteins outside bacterial cells. The best-known pathway is the GSP. However, many flagellar proteins cannot pass through this system, since they do not have the signal sequences that are necessary for the recognition by GSP.

To date, there are six characterized bacterial protein secretion systems (type I–VI) that are grouped according to their function in pathogenesis. Here I will briefly explain the major three types of export systems.

Type I secretion system (T1SS) secretes proteins without modification through the secretion apparatus consisting of a few component proteins that span both the inner and the outer membranes, for example, hemolysin in *E. coli*.

Type II secretion system (T2SS) secretes proteins retaining the signal peptide, which is cleaved upon secretion by GSP, for example, pullulanase in *Klebsiella oxytoca*. Thus, GSP is a secretion machinery in T2SS.

Type III secretion system (T3SS) secretes proteins without cleavage through the gigantic secretion apparatus spanning both the inner and the outer membranes, for example, virulence factors (or effectors) from many pathogenic *Enterobacter* spp. The flagellar protein export system is now regarded as a T3SS. The secretion gate of the flagellar export apparatus consists of five components (FlhA, FlhB, FliP, FliQ, and FliR). The amino acid sequences of these proteins share homology with those for secretion of effectors in many pathogenic bacteria. The structures between these two distinguishable systems resemble each other; the secretion apparatus for effectors is the needle complex, which looks like the flagellar basal body, consisting of several ring structures and a needle. It is now suspected that flagellum and pathogenesis might be derived from a common ancestor.

The two secretion systems are superficially independent from each other in *S. typhimurium*. However, it is now known that the *Salmonella* pathogenesis island (SPI) 1 gene expression is regulated by a flagellar gene *fliZ* in serovar Typhimurium and is dependent on flagellar sigma factor FliA in serovar Typhi. Note that *fliA* and *fliZ* sit next to each other in an flagellar operon.

The Kinetics of Morphogenesis

The morphological pathway of the flagellum described above indicates the order of the construction steps but ignores the time to be consumed at each step. In order to achieve coherent cell activities, flagellar construction has to be synchronized with cell division. The most time-consuming step of flagellation seems to be the first step, the construction of the export apparatus, which takes almost one generation to complete. The filament elongation also takes time; filaments grow over generations in peritrichously-flagellated cells. The growth processes of the filament and the hook have been carefully analyzed. By taking a closer look at elongation modes of these two polymers, we will get a glimpse of the whole kinetic process of flagellar construction.

Filament Growth

In bacteria with peritrichous flagella, the number and the length of flagella are, if not exactly, fairly well defined; there are 7–10 flagella per cell and the average length of filament is 5–8 μm .

A defined number of flagella have to be supplied at each cell division. A large deviation from this number will cause disastrous results to the cell—either no flagella at all or too many to swim. The number of flagella must be genetically controlled, but the gene(s) for this role has not been identified.

On the other hand, filament growth is dependent on physiological conditions and it continues over generations. Although filament length seems free from genetic control in peritrichous flagellated bacteria, it is genetically controlled in polarly-flagellated species; the *flaG* gene is suggested to control of flagellar length in *C. jejuni*.

From statistical analysis of the length distribution, the elongation rate of filaments is inversely proportional to the length; thus, a filament grows rapidly in the beginning and gradually slows down to a negligible rate. Direct observations of growth rate of individual filaments have been attempted using fluorescent labeling method. In a short range, the growth rate is constant, whereas in a long range the rate changes from quick to slow, agreeing with the statistical data.

Hook Growth

In contrast to the wide distribution of filament lengths, hook length is rather well controlled at 55 nm with a deviation of 6 nm. Hook length is controlled by a secreted protein FliK; deletion of the *fliK* gene results in hooks with undefined length, called polyhooks. Engineered FliK, either elongated by insertion of foreign sequences or shortened by internal deletions, gives rise to hooks whose length is proportional to the molecular size of the mutant FliK. Thus, FliK is a molecular ruler. In 2014, we showed that FliK determined the minimal length of the hook; hooks shorter than 30 nm have been rarely observed. On the other hand, polyhooks (in a *fliK*-deletion mutant) are ready to form filament immediately after FliK is expressed from a plasmid. Therefore, FliK does not have to measure hook length but simply switches the secretion gate into the mode for FlgM to be secreted. Next, we want to know how FliK passes through the gate without switching to occur when hook length is still short.

Statistical analysis of the length distribution of polyhooks reveals that the hook grows in a similar manner as the filament does; it starts outgrowing at 40 nm min^{-1} and exponentially slows down to reach a length of 55 nm. After the length is 55 nm, the hook grows at a constant rate of 8 nm min^{-1} . It takes many generations for polyhooks to grow as long as several micrometers. We have also known that mutations in switch proteins (FliG, FliM, and FliN) gave rise to short hooks with a defined length. Therefore, kinetics of substrate secretion would be involved in this event, though relationship between FliK and the C ring cup has been unsolved. Studies of the correlation between flagellation and cell division are under way, but no definite schemes have been found.

Conclusion

In previous editions, I wrote, “Analysis of the flagellar structure has been coming to an end”; but since then many unexpected facts were revealed. We are proud of the brilliant results of our research; most components of the flagellum were identified, some of the substructures including the filament and the hook were solved at the atomic resolution, the pathway of flagellar construction has been revealed, and roles of ca. 40 flagellar genes in the flagellar construction are now known. However, I now realize that nature is not so shallow to reveal everything in the short life of a man. We have to keep asking “Why?” with indefatigable enthusiasm to unveil mysteries of the flagellum.

We do not yet know the physics principles of flagellar rotation. One of the immediate goals is to answer a simple but important question; what is rotating against what and how? This question stems from the controversy that has started from the beginning of flagellar research. Without knowing the rotor and the stator in detail, the mechanism of motor function will never be understood. And then, we want to answer a more intriguing and difficult question: what is the ancestor of the flagellum? The question arose from the recent discovery of similarity between the flagellum and pathogenicity: (1) the supramolecular structures of the flagellum and the needle resemble each other, and (2) the gene sequences of the major components in their basal structure are homologous. This also leads us to the most primitive question: what is the flagellum?

Bacterial Iron Acquisition Strategies

Neal D Hammer, Michigan State University, East Lansing, MI, United States

Introduction

Iron is a fundamental building block for life. The dynamic oxidation states of this transition metal are required for the catalysis of many essential biochemical reactions. Consistent with this, iron typically exists in the ferric (+3) or ferrous (+2) oxidation states. However, the ease with which iron transitions between these oxidation states and its low solubility at neutral pH are two problems organisms must solve. The solution is to complex iron within cofactors or proteins. Thus, this highly reactive atom is rarely “freely” available to react with sensitive molecules within organisms. Iron-containing cofactors and proteins allow cells to harness the chemical dynamism of iron without the associated toxicity or insolubility. Numerous chemical reactions involved in central metabolism, nucleotide synthesis, and the detoxification of reactive oxygen and nitrogen species are catalyzed by enzymes that contain one or more iron atom, underscoring the essentiality of iron to cellular physiology.

An additional benefit of maintaining low levels of “free” iron is the challenge that the limitation imposes on invading bacterial pathogens. Most pathogens, like their hosts, require iron to perform essential biochemical reactions, but pathogens are completely dependent on sources of iron present within the host environment to fulfill this requirement. The host exploits this requirement and utilizes multiple mechanisms to impede pathogen iron procurement. The process of inhibiting the proliferation of invading bacteria by obstructing access to essential nutrients, such as iron, is called “nutritional immunity”. To overcome nutritional immunity, bacterial pathogens have evolved sophisticated systems to procure iron from the host environment. The focus of this article includes the sources of iron available to pathogens within the host and the strategies bacterial pathogens employ to acquire and maintain iron homeostasis.

Sources of Iron Within the Host

Low solubility at physiological pH and a high propensity for oxidation necessitate that iron be complexed to a molecule. Numerous iron-binding molecules present in the host achieve this goal. In vertebrates, iron is predominantly bound to proteins or the tetrapyrrole heme. Iron-binding and heme-binding proteins also sequester iron from invading bacteria. Additionally, iron is principally contained within host cells, further obstructing the accessibility of this metal to pathogens. Extracellular iron is bound by high-affinity iron-binding proteins such as ferritin, transferrin, and lactoferrin. Extracellular heme is sequestered by hemopexin. Together, these mechanisms of iron sequestration ensure that the host environment is relatively limited in “free” iron. However, pathogens have evolved elegant systems to extract iron from these proteins.

The most abundant iron-containing molecule in vertebrates is the tetrapyrrole heme. Consequently, many pathogens encode heme acquisition systems to steal heme-iron from the host. Heme is predominantly complexed to the protein hemoglobin within erythrocytes. In this context, heme functions to transport oxygen to and carbon dioxide away from host tissues. Consistent with this, erythrocyte lysis is a virulence trait associated with many bacterial pathogens, and this trait functions to liberate a great deal of iron in the form of heme-bound hemoglobin. Pathogens express elaborate systems composed of dedicated hemoglobin and heme receptors, as well as, transport proteins that import and degrade host heme, fulfilling the iron requirement. However, because iron can yield highly reactive hydroxyl radicals through the Fenton reaction, which are toxic at high concentrations, the systems that function to scavenge iron or heme from the host environment are under strict transcriptional control. As such, pathogens express iron acquisition systems only when the cell resides within iron deplete environments. In most bacteria this transcriptional control is achieved by the ferric uptake regulator, Fur.

Transcriptional Control of Iron Acquisition Systems

Despite the abundance of iron within vertebrates, iron-binding proteins and the vast intracellular reservoirs are not readily available to invading pathogens. Therefore, upon breach of protective barriers and invasion into tissues, the pathogen encounters an iron-deplete environment. Concomitantly, the microbial invaders upregulate genes encoding iron acquisition systems. Fur is the master transcriptional regulator of iron acquisition systems and Fur-dependent transcriptional control is achieved via a canonical mechanism of repression. Within the bacterial cytoplasm, Fur binds excess iron and represses the expression of iron acquisition systems. Repression of target transcripts is mediated by the high affinity of iron-bound Fur for consensus DNA sequences present within the promoter sequences of genes encoding iron acquisition systems. Fur binding blocks RNA polymerase, resulting in transcriptional repression. When iron becomes limiting, the amount of intracellular iron decreases. This causes the release of iron from Fur and subsequent reduced DNA-binding affinity for the Fur consensus sequence. Consequently, the target promoter becomes accessible to RNA polymerase that transcribes iron acquisition genes. Fur is conserved in both Gram-positive and

Gram-negative pathogens, and locating the Fur consensus sequences within bacterial genomes has led to the identification of many of the iron acquisition systems discussed below. The importance of this transcriptional regulator is demonstrated by the profound virulence defects of *fur* mutants. Additionally, Fur activity ensures that iron acquisition systems are expressed exclusively in iron-deplete environments. Unregulated expression of these systems is energetically costly to the bacterium in iron-replete conditions when iron import is not needed. Constitutive import of iron is also detrimental to bacterial cells as excessively high levels of iron can lead to production of damaging reactive oxygen species through the Fenton reaction. Therefore, while iron is crucial to bacterial proliferation, regulation of these systems is equally as important.

Siderophore-Mediated Iron Acquisition

A major class of Fur-regulated genes encode enzymes that synthesize low molecular weight (<1 kDa), ferric (Fe^{3+}) iron-binding compounds called siderophores. The high affinity siderophores have for ferric iron allows these molecules to outcompete most host proteins. For example, the ferric binding constants of siderophores have been reported to be as high as 10^{-52} M, which is much greater than the binding constant of transferrin, 10^{-23} M. Siderophore-mediated iron acquisition is a common iron procurement strategy that is widely conserved among pathogenic and non-pathogenic bacteria but also fungi, yeast, and animals. Consistent with this, over 500 different siderophores have been described. Often, different species of bacteria produce identical siderophores; however, some pathogens produce unique siderophores to prevent competing microbes from stealing their siderophore. In bacteria, the genes involved in siderophore biosynthesis and import are typically present within a single operon (Fig. 1). Specifically, these operons usually consist of biosynthetic enzymes, siderophore efflux pumps, siderophore-iron complex importers, and accessory proteins that aid in siderophore function. The operons present in Gram-negative bacteria also contain outer membrane-localized receptors specific to a particular siderophore. The importance of siderophores to bacterial pathogenesis has been established in numerous studies demonstrating that mutant strains devoid of siderophore production are severely attenuated in many different models of infection. Additionally, a number of pathogens synthesize more than one siderophore and mutant strains that are restricted to the synthesis of a single siderophore often demonstrate organ-specific virulence defects. These findings demonstrate the temporal and spatial specificity between different siderophores and have prompted investigators to evaluate the potential of siderophores as vaccine candidates. Thus far, two reports demonstrate that immunization with siderophores mounts an effective host immune response that reduces bacterial burdens within the vaccinated host. Thus, host antibodies that bind the siderophore can be generated that obstruct siderophore-mediated import of host iron into the pathogen.

Siderophores are classified into five different families based on the chemical signature of the iron-binding moiety. Catecholate, phenolate, hydroxamate, and α -hydroxycarboxylate represent four of the five classifications. The fifth classification represents mixed siderophores that contain more than one iron-binding moiety. Siderophore synthesis occurs via one of two mechanisms. The first

Fig. 1 The genes encoding siderophore-mediated iron acquisition systems are often located in close proximity within the genome. (A) An illustration of the genes required for enterobactin synthesis in *E. coli*. (B) Proteins encoded by the *iro* genes synthesize, import, and degrade the stealth siderophore salmochelin. (C) Production of the siderophores staphyloferrin A and staphyloferrin B is conserved in the Gram-positive pathogen *S. aureus*. The *sbn* operon encodes the proteins needed to facilitate staphyloferrin B synthesis and import. The SirABC complex is an ABC transporter. The ATPase that generates the energy needed for staphyloferrin B import is FhuC, which is encoded elsewhere in the genome. The functions of the proteins encoded by the genes are based on reference material or UNIPROT analysis. The genes not drawn to scale.

mechanism is dependent on large multi-enzyme complexes called non-ribosomal peptide synthetases (NRPSs) that bind precursor molecules and catalyze siderophore synthesis using energy generated from ATP hydrolysis. Specific genes within the siderophore operon create the precursor molecules needed for the NRPS. Next, the precursor molecules are assembled into the siderophore product with the aid of other enzymes present within the NRPS complex. Alternatively, siderophore biosynthesis can occur independently of the NRPS. The NRPS-independent pathways are not as well studied; however, recent reports have shown NRPS-independent siderophores contain their own synthetases within the siderophore operon that catalyze the formation of amide or ester bonds between the precursor molecules via condensation reactions. In both systems, the final product is then effluxed from the bacterium using dedicated, membrane-bound exporters.

Upon siderophore binding of iron in the extracellular space, the molecule undergoes a conformational change, allowing the iron-siderophore complex to be recognized by specific bacterial cell surface receptors expressed within the outer membrane of Gram-negative bacteria. This interaction facilitates import. The outer membrane-localized receptors typically consist of a beta-barrel structure with a domain inside the barrel that creates a “plug”. Studies have shown that reconfiguration of the “plug” domain allows for the passage of the siderophore-iron complex through the barrel. The energy needed to traffic the siderophore across the outer membrane and into the periplasm is provided by the TonB complex. This complex, consists of three proteins, TonB, ExbB, and ExbD, utilizes the proton motive force (PMF) to couple energy from the inner membrane to drive import of the substrate. Once the iron-siderophore complex is transported into the periplasm, transporters of the ATP-binding cassette (ABC) superfamily are responsible for passage of the complex across the inner membrane and into the cytoplasm. The energy required for this transport is generated via ATP hydrolysis. Gram-positive bacteria also use ABC transporters to import the siderophore-iron complex. ABC transporters typically consist of three distinct functional units: a lipoprotein that binds the siderophore-iron substrate in the periplasm (or within the cell envelope in the case of Gram-positive bacteria), a permease composed of two proteins located within the cytoplasmic membrane that function as the channel through which the siderophore-iron complex traverses, and a cytoplasmic ATP hydrolysis enzyme. Typically, the genes encoding a siderophore ABC transporter are located in close proximity within the genome to the genes encoding the siderophore biosynthesis enzymes (Fig. 1). However, some pathogens express orphan ABC transporters that promiscuously import siderophores produced by other bacteria.

Once in the cytoplasm, iron must be liberated from the siderophore for it to be utilized in various enzymatic processes. Two unique mechanisms facilitate the release of iron from the siderophore. The first mechanism is mediated by enzyme called ferrisiderophore reductases that catalyzes the reduction of ferric iron, Fe^{3+} , to ferrous iron, Fe^{2+} . Because siderophores bind Fe^{2+} with a lower affinity than Fe^{3+} , the Fe^{2+} is easily extracted. Alternatively, some bacteria release iron through enzymatic hydrolysis of the siderophore; however, this disrupts the integrity of the complex and is costly because the siderophore is unable to be reused. Therefore, an advantage of the reductase-mediated strategy of iron release is that the siderophore can be recycled to retrieve another Fe^{+3} atom.

In the continuous battle between host and pathogen, vertebrates are equipped to impede siderophore-mediated iron acquisition. The lipocalin family of proteins function to bind and sequester catecholate- and phenolate-type siderophores. For instance, lipocalin 2 (also referred to as 24p3, NGAL, or siderocalin) binds enterobactin, a siderophore commonly produced by species within the family *Enterobacteriaceae*. The importance of this siderophore countermeasure is demonstrated by the observation that lipocalin 2-deficient mice are more susceptible to infections caused by Gram-negative bacteria. In response to the selective pressure applied by the lipocalin family of proteins, pathogens adapted by evolving mechanisms to chemically modify their siderophores, blocking recognition by host siderophore-binding proteins. These so called stealth siderophores contain slight chemical modifications to an existing siderophore, maintaining the high affinity for iron but abolishing recognition by lipocalin family of host proteins (Fig. 1(B)). For example, *Escherichia coli* synthesizes the siderophore enterobactin, which is bound by lipocalin 2. However, some strains of *E. coli* also encode the enzyme, *iroB*, which glycosylates enterobactin, resulting in a modified enterobactin called salmochelin. Lipocalin 2 fails to bind salmochelin, allowing the stealth siderophore to bypass host sequestration of enterobactin such that *E. coli* can achieve unperturbed acquisition of host iron. In addition to the synthesis of stealth siderophores, many pathogens are also equipped with the capacity to scavenge siderophores produced by other bacterial species. Together these mechanisms enhance the iron acquisition strategies of invading pathogens ensuring that the requirement for iron is satisfied during infection.

Iron Acquisition Through Targeting Host Heme

Heme represents the most abundant iron-containing molecule in vertebrates. Not surprisingly, many pathogens, especially those capable of proliferating with the vasculature, target host heme to fulfill the iron requirement. Heme acquisition begins with the lysis of erythrocytes, liberating the enclosed hemoglobin. Each hemoglobin binds four heme molecules and each erythrocyte contains approximately 270 million hemoglobins. Therefore, lysis of one erythrocyte results in a tremendous potential yield of iron for the pathogen. Hemolytic activity via hemolysins is a virulence trait associated with many Gram-positive and Gram-negative pathogens.

Some pathogens are equipped with additional mechanisms that facilitate acquisition of heme from reservoirs less abundant than hemoglobin. One example is the heme-binding protein hemopexin that functions to alleviate heme-mediated damage to host tissues. The high reactivity of heme requires that the molecule be complexed to proteins to prevent illicit damage to other host molecules. Consequently, the amount of ‘free’ heme is kept low in order to protect tissues from heme-induced redox damage. Hemopexin functions in this capacity and is a viable source of heme-iron for Gram-positive and Gram-negative pathogens such as

Bacillus anthracis and *Serratia marcescens*, respectively. Not all pathogens are capable of stealing heme from hemopexin. A notable exception is the important human pathogen *Staphylococcus aureus*. For the pathogens that do, a common strategy is to procure the hemopexin heme using a siderophore-like mechanism that outcompetes hemopexin for heme. In the case of *S. marcescens*, the protein that facilitates this competition is a hemophore called HasA. HasA has a higher affinity for heme than hemopexin. This allows HasA to retrieve heme from host hemopexin. The production of hemophores is not limited to Gram-negative pathogens as the Gram-positive pathogen, *B. anthracis* also utilizes hemophores to scavenge host heme from hemopexin and other sources.

The Gram-Positive Iron-Regulated Surface Determinant System

Gram-positive pathogens acquire host heme utilizing the iron-regulated surface determinant (Isd) system. Isd function can be divided into four distinct steps (Fig. 2(A)). Generally, these steps include (i) binding of extracellular heme or heme-containing proteins, (ii) stripping the heme from the host protein and transporting it across the cell wall, (iii) importing the heme into the bacterial cytoplasm, and (iv) degradation of heme, releasing free iron. Each step is performed by one or more proteins that together support pathogen heme acquisition. The importance of the Isd system to pathogenesis is underscored by conservation of the system in numerous Gram-positive pathogens, as well as, the virulence defects observed in multiple species genetically inactivated for any one of the Isd proteins.

The process of Isd-mediated heme-iron acquisition is initiated by extracellular receptors covalently bound to the surface of the peptidoglycan in the cell wall. These receptors bind heme or heme-containing host proteins. Consistent with their localization at the cell surface, the amino acid sequence of the receptors contains canonical Sec translocon signal sequences and conserved sortase A (SrtA) recognition domains. The receptors are endowed with distinct affinities for heme or hemoglobin (Fig. 2(A)). Haptoglobin, a host protein that binds hemoglobin to initiate hemoglobin recycling, is also a target of Isd receptor proteins (Fig. 2(A)). *S. aureus* expresses several Isd receptors that bind specific heme reservoirs. These receptors function in the sequential transport of heme to other Isd proteins embedded within the cell wall. For example, IsdH and IsdB bind haptoglobin and hemoglobin, respectively

Fig. 2 Heme acquisition strategies employed by bacterial pathogens. (A) The iron-regulated surface determinant system (Isd) expressed by Gram-positive pathogens is required for heme acquisition from the host environment. Heme or heme-containing proteins are bound by the surface-exposed receptors IsdH, IsdB, or IsdA. Heme is subsequently transferred between these proteins via near-iron transporter (NEAT) domains to the cell wall (CW)-embedded protein IsdC. In some Gram-positive species, the hemophores, IsdX1 or IsdX2, steal heme from host hemopexin and transfer the heme directly to IsdC. IsdC transfers heme to the membrane (M)-localized ABC transporter IsdDEF. The heme is then imported into the cytoplasm where it is a substrate for the Isd-family of heme oxygenases, IsdG or IsdI which liberate the iron atom. (B) This illustration depicts the Gram-negative heme acquisition systems. Hemophore-dependent heme acquisition is also a strategy employed by some species of Gram-negative pathogens. In this depiction, the hemophore, HasA, retrieves host heme from hemopexin and transfers the heme to its receptor, HasR. Heme can also be captured by outer membrane (OM)-localized heme receptors. In this model the receptors are Hma and ChuA, but over 30 OM-localized heme receptors have been described. Typically, Gram-negative species employ either hemophore-mediated or receptor-mediated heme acquisition. Using energy derived from the PMF, the TonB complex facilitates import of heme to the bacterial periplasm. ChuT functions as a periplasmic chaperon that traffics the heme to the ChuUV ABC transporter. In the cytoplasm, heme is degraded by heme oxygenases to liberate iron. This degradation results in unique products depending on the presence or absence of oxygen.

(Fig. 2(A)). Binding of the host-derived substrate is mediated by a unique domain referred to as the near iron transporter or NEAT domain, which binds heme or heme-containing proteins with high affinity. In keeping with this, IsdH contains three NEAT domains while IsdB has two. The NEAT domains coordinate binding and trafficking of heme-containing proteins or heme between the Isd receptor proteins (Fig. 2(A)). IsdA expressed on the surface of *S. aureus* contains a single heme-binding NEAT domain. Consistent with this, IsdA functions as an independent heme receptor but can also receive heme from IsdB or IsdH. IsdB is sufficient for *S. aureus* utilization of heme or hemoglobin as sources of iron, but the redundant heme-binding activities of IsdH, IsdB, and IsdA allows for maximal flexibility of pathogen heme-iron acquisition. Some Gram-positive species, such as *B. anthracis*, encode hemophores that allow the pathogen to target heme bound to hemopexin. *B. anthracis* secretes two hemophores, IsdX1 and IsdX2 that steal heme from hemopexin (Fig. 2(A)). Once the hemophores and receptor proteins have isolated heme, the molecule is trafficked through the cell wall, a hallmark of the next phase of Isd-mediated heme-iron acquisition.

The two steps that follow receptor binding of host heme are transporting heme through the thick peptidoglycan and importing the molecule into the cytoplasm (Fig. 2(A)). Heme is transferred across the peptidoglycan layer by IsdC. In keeping with its function as a heme-binding protein, IsdC also contains a NEAT domain. A feature that distinguishes IsdC from the surface-exposed receptors is the enzyme that covalently links IsdC to the peptidoglycan, Sortase B (SrtB). The current model suggests that SrtB-mediated anchoring of IsdC facilitates localization of IsdC throughout the peptidoglycan. Consistent with this, IsdC is the only known SrtB substrate. In addition, both IsdC and SrtB are encoded within the *isd* operon, providing further evidence that these proteins function in a concerted effort to aid transport of host-derived heme through the Gram-positive cell wall. This model implies that heme is sequentially passed between multiple IsdC proteins that work in a bucket brigade-like fashion to transport heme through the peptidoglycan to the membrane-localized heme importer. Once at the membrane, IsdC passes heme to a conical ABC transporter consisting of the IsdD, IsdE, and IsdF proteins. These proteins are also encoded within the *isd* operon and use energy derived from the hydrolysis of ATP to import heme into the cytoplasm. Once in the cytoplasm, the Isd system contains dedicated enzymes that liberate iron from heme.

The final step of heme-iron acquisition is heme degradation. Heme is degraded by enzymes called heme oxygenases that cleave the tetrapyrrole ring, liberating the iron atom. In *S. aureus* heme degradation is catalyzed by two oxygenases, IsdG and IsdI (Fig. 2(A)). Until recently, bacterial heme degradation was thought to proceed in a similar fashion as mammalian heme degradation. However, studies that focused on the mechanistic details of IsdG and IsdI enzymatic activity, including the discovery of a novel heme degradation product, revealed that heme degradation in Gram-positive species is distinct from heme degradation in mammalian and Gram-negative bacteria. The distinguishing characteristic between the two mechanisms are the products resulting from the cleavage of the tetrapyrrole ring. Heme oxygenases expressed in mammals and Gram-negative species degrade heme to a molecule called biliverdin and carbon monoxide. However, IsdG and IsdI degrade the heme yielding a molecule called staphylobilin and formaldehyde. In mycobacterial species, yet another heme degradation product has been discovered called mycobilin. That different bacterial species degrade heme to unique products supports the intriguing hypothesis that the heme degradation products also have a function. Consistent with this, in vertebrates, biliverdin is converted to bilirubin, a potent antioxidant. However, specific functions of the heme degradation products in bacterial species has yet to be elucidated.

Gram-Negative Heme Acquisition Systems

Gram-negative pathogens also target heme-containing hemoglobin as a source of iron. First, the pathogen lyses erythrocytes to liberate hemoglobin from these cells and initiate heme acquisition. To accomplish this, *S. marcescens* and *E. coli* rely on the hemolysins ShlA and HylA, respectively. Gram-negative bacteria capture the heme liberated via hemolysis utilizing two distinct mechanisms: direct heme binding to outer membrane receptors or secretion of hemophores that scavenge for host heme, subsequently passing the heme to their cognate receptor (Fig. 2(B)). Some Gram-negative bacteria possess both hemophore-mediated and receptor-mediated systems; however, it is more common for the pathogens to employ one or the other. Two heme receptors have been extensively characterized in uropathogenic *E. coli*, ChuA and Hma, but more than 30 heme receptors have been described in Gram-negative species (Fig. 2(B)). Outer membrane heme receptors are similar to the iron-siderophore complex receptors described above both in terms of structure and the utilization of the proton motive force (PMF) to drive import. Heme receptors are β -barrels that encode specific residues within extracellular domains that bind heme. Two of these domains, FRAP and NPFL, contain conserved amino acid motifs in the extracellular loops of outer membrane receptors that are critical for heme import. These domains function to bind heme and transport it through the outer membrane. The β -barrel heme receptors rely on the TonB protein complex to couple energy (PMF) from the inner membrane to power heme import.

Gram-negative pathogens also utilize hemophores to retrieve host heme. One of the best-described hemophores is HasA produced by *S. marcescens*. The heme acquisition system (Has) consists of the hemophore and its outer membrane receptor, HasR. Analogous systems have been characterized in *Pseudomonas aeruginosa* and *Yersinia pestis*. HasR is structurally similar to the β -barrel heme receptors but heme binding is significantly enhanced when it functions in concert with HasA. HasA is secreted as a dimer and conserved tyrosine and histidine residues coordinate within a pocket to facilitate heme binding. These residues are critical for heme binding. HasR recognizes monomeric HasA; therefore, the function of the HasA dimer is not well understood. Once HasR binds HasA, both proteins undergo conformational changes leading to the exchange of heme from HasA to HasR.

Periplasmic binding proteins (PBPs) are responsible for shuttling heme from the outer membrane through the periplasm to the inner membrane (Fig. 2(B)). PBPs that bind heme, such as ChuT, have been identified in *P. aeruginosa*, *Shigella dysenteriae*, *E. coli* and *Y. pestis*. Similar to HasA, PBPs coordinate heme binding using a conserved tyrosine residue within a cleft connecting the N- and C-termini. The heme-binding PBPs then pass the heme to dedicated ABC transporters. Analogous to siderophore import, ABC transporters hydrolyze ATP to mediate heme delivery to the cytoplasm. While the outer membrane receptors for both siderophores and heme are incredibly substrate specific, the ABC transporters do not seem to be. For example, *P. aeruginosa* encodes approximately 34 TonB-dependent outer membrane receptors, but only four ABC transporters function in iron import. Therefore, it is likely that the same ABC transporters used for siderophore-iron import are also used to import heme.

Gram-negative bacteria employ heme oxygenases to degrade heme. However, the enzymes expressed in Gram-negative species are distinct from the LsdG-family heme oxygenases expressed in Gram-positives. Consistent with this, the products of the Gram-negative heme degradation reaction are iron, biliverdin and carbon monoxide (Fig. 2(B)). A new mechanism of heme degradation has recently been reported in the Gram-negative pathogen, enterohemorrhagic *E. coli* O157:H7. In aerobic environments canonical heme oxygenases catalyze the release of iron from heme, using oxygen as a cofactor. However, bacteria capable of growing in anaerobic environments such as the intestines, must have alternative mechanisms to liberate iron from heme without oxygen. *E. coli* O157:H7 encodes an operon for heme uptake that includes three additional uncharacterized genes, *chuW*, *chuX*, and *chuY*. Elegant biochemical experiments demonstrated that ChuW uses the oxidizing potential of a carbon radical to free heme-bound-iron through a methyl transfer reaction leading to the rearrangement of the heme porphyrin ring. The complete mechanism of this reaction is currently not known; however, ChuW catabolizes the porphyrin ring of heme yielding free iron and a tetrapyrrole called anaerobilin (Fig. 2(B)). ChuY breaks down and reduces anaerobilin, a potentially toxic product of heme degradation. *chuW* and *chuY* are co-transcribed, suggesting a comprehensive mechanism of anaerobilin synthesis by ChuW after iron liberation from heme followed by anaerobilin reduction by ChuY.

Circumventing Heme Toxicity

To harness the redox potential of heme, organisms complex the tetrapyrrole to proteins. Thus, the quantity of 'free' heme within cells is low. However, in the absence of protein binding, the unharnessed redox potential of 'free' heme is reactive with proteins and other molecules within cells. Moreover, as a hydrophobic molecule, 'free' heme aberrantly interacts with membranes potentiating the resulting toxicity. Thus, organisms that encounter 'free' heme must have strategies to counteract this toxicity. The host protein hemopexin is one such example, but how do bacterial pathogens that target host heme to satisfy their iron requirement deal with heme associated toxicity? In general, Gram-negative pathogens are more resistant to the toxic effects of heme than Gram-positive pathogens. One such example is *S. dysenteriae*, which rapidly degrades heme to reduce its toxic effects. Gram-positive pathogens, on the other hand, encode systems such as the heme-regulated transporter, HrtAB that protects the bacterial cell from heme toxicity. The HrtAB transporter is a canonical ABC transporter, composed of an ATPase, HrtA, and a permease, HrtB. The current model of HrtAB-mediated heme detoxification predicts that these proteins function to efflux heme from the bacterial cytoplasm. HrtA hydrolyzes ATP to generate the energy needed to pump heme from the bacterial cytoplasm across the plasma membrane through HrtB, allowing the cell to reduce intracellular levels of 'free' heme.

HrtAB is widely conserved in Gram-positive pathogens, as well as, non-pathogenic species such as *Lactococcus lactis*. Notably, pathogens and commensals have evolved unique ways to regulate HrtAB expression. Pathogens utilize a dedicated two-component system (TCS) called the heme-sensing system, HssRS that regulates expression of HrtAB efflux pump. HssRS functions as a canonical TCS. Phosphorelay from the membrane-bound sensor, HssS, to the response regulator, HssR, induces expression of HrtAB. The precise molecular signal that stimulates HssRS activation and phosphorelay, remains elusive, however, heme is an absolute requirement. An alternative mechanism of HrtAB regulation was discovered in *L. lactis*, a bacterium typically associated with plants that is used extensively in the production of cheese and other dairy products. In *L. lactis*, a cytoplasmic-localized transcriptional regulator, HrtR induces HrtAB expression. HrtR represses expression of HrtAB in the absence of heme, but upon heme binding, the affinity of HrtR for DNA decreases relieving HrtAB repression. Why Gram-positive species evolved two different mechanisms to regulate the HrtAB heme efflux pump transporter remains to be elucidated. However, it is clear that HrtAB, and HssRS or HrtR act in a concerted manner to effectively manage heme homeostasis ensuring that Gram-positive bacteria circumvent heme toxicity.

Coordinating the Iron Acquisition Systems

Heme and iron are exceedingly toxic at high levels. Therefore, bacteria that target both siderophore-mediated and heme-mediated iron acquisition systems must coordinate expression of the acquisition systems to maintain iron homeostasis without corresponding toxicity. It is likely that the abundance of different iron-containing molecules is dramatically altered in different host tissues. In keeping with this, siderophore-mediated iron acquisition may be better suited for colonization of distinct organs or tissues compared to heme-mediated acquisition systems and vice versa. Together these facts require that bacteria coordinate the expression of the acquisition systems to maximize fitness during infection of distinct niches. We are just beginning to understand the interplay

between the iron acquisition systems but a recently described transcriptional regulator expressed in *S. aureus* has emerged that serves as the paradigm for coordination of iron acquisition systems.

SbnI is a transcriptional regulator encoded within one of the *S. aureus* siderophore synthesis operons (Fig. 1(C)). *S. aureus* produces three siderophores, a nicotinamine-like broad spectrum metallophore called staphylopin and two α -hydroxycarboxylate siderophores: staphyloferrin A and staphyloferrin B. The *sbn* operon encodes the genes required for staphyloferrin B synthesis. *sbnI* is the terminal gene of a nine gene *sbn* operon. The function of SbnI remained elusive, but SbnA-H function to synthesize or efflux staphyloferrin B (Fig. 1(C)). Recent, elegant work demonstrated that SbnI enhances the expression of *sbnD-H* in conditions of low iron. Notably, SbnI-dependent expression of *sbnD-H* is affected by the presence of heme. SbnI is capable of binding heme and this reduces the affinity SbnI has for its DNA promoter sequence within the *sbnD* gene. In the presence of heme the expression of *sbnD-H* is decreased, reducing the production of staphyloferrin B. Therefore, SbnI coordinates the production of staphyloferrin B in iron-deplete environments devoid of heme. However, in iron-deplete environments containing heme, staphyloferrin B is not produced. This elegant coordination of heme- and siderophore-mediated iron acquisition maximizes *S. aureus* fitness by ensuring that the iron requirement of the pathogen is satisfied.

The EfeUOB/FepABC Iron Acquisition System

The EfeUOB, and analogous FepABC system facilitate iron acquisition in both Gram-positive and Gram-negative pathogens. However, the mechanism by which this system functions in iron acquisition is debated. Much of the debate centers on the function of EfeB, or FepB, as two competing models have emerged. In the first model, EfeB functions as a deferriochelate. That is to say that EfeB/FepB extracts iron from heme leaving the porphyrin ring intact. Therefore, this model predicts that heme is the target of the EfeB/FepB. Alternatively, it has been demonstrated that the FepB protein in *Listeria monocytogenes* reduces ferric iron to ferrous iron. This study serves as the foundation for the second model which implies the target for the Efe/Fep system is ferric iron. Additional investigation is needed to define how FepB and EfeB function in iron acquisition. The two other components of the tripartite system, EfeU/FepC and EfeO/FepA are more clearly defined. EfeO/FepA chaperones the ferrous molecule that results from the EfeB/FepB reaction to the permease encoded by EfeU/FepC. EfeU/FepC then transports the iron atom into the cytoplasm.

Concluding Remarks

As iron is a requirement for bacterial proliferation and survival, it is not surprising that pathogens evolved multiple mechanisms that target the most abundant sources of iron within their hosts. One mechanism utilizes the production of low molecular weight siderophores that outcompete host iron-binding proteins to procure the essential metal. A second mechanism, often also employed by bacteria that synthesize siderophores, targets the most abundant iron-containing molecule in vertebrates, heme. To acquire heme-iron, Gram-positive and Gram-negative pathogens secrete hemolysins that liberate the molecule from erythrocytes. The heme is then targeted by proteins that facilitate its import and degradation resulting in the release of nutrient iron (Fig. 2). This multifaceted strategy ensures that pathogens are able to fulfill their iron requirement during infection. Maintaining more than one system dedicated to the procurement of iron seems redundant. However, the quantity of iron and the chemical moieties that sequester iron within the host varies between sites of infection. Therefore, encoding multiple iron acquisition systems allows pathogens to fine-tune iron acquisition in the diverse and dynamic environments encountered during infection. There is much to be learned about how these two strategies are regulated and how they can be exploited to advance novel therapies that combat antibiotic-recalcitrant bacterial infections.

Bacterial Targeting of Tumors

Origins of Live Bacteria for the Treatment of Cancer

The concept that bacteria might have beneficial effects against cancer has several potentially independent origins. In 1813, Vautier reported that tumor regressions sometimes occurred patients with gas gangrene, the disease now known to be caused by anaerobic members of the genus *Clostridium* (as cited by Mowday et al., 2016). Live *Clostridium* were later explored in several early studies as antitumor agents (e.g., Parker et al., 1947; Möse and Möse, 1964; Carey et al., 1967), and more recently were genetically engineered to improve safety and antitumor activity (e.g., Minton et al., 1995; Fox et al., 1996; Dang et al., 2001; Nuyts et al., 2002). An attenuated *Clostridium novyi* strain is currently undergoing clinical trials (Roberts et al., 2014). Because tumors have irregular vasculature, they are often hypoxic or anoxic, which provides a suitable habitat for these anaerobic bacteria. Another anaerobic bacteria that has also been explored as antitumor agents is *Bifidobacterium longum* (e.g., Taniguchi et al., 2016), which is non-pathogenic.

Following the early report by Vautier, antitumor effects were noted in association with erysipelas (Busch, 1866; Fehleisen, 1883; Bruns, 1887), the disease now known to be caused by Group A *Streptococcus*. Based on the studies of Fehleisen and Bruns, the American surgeon William B. Coley began experimenting with administering live erysipelas organisms (then referred to as *Streptococcus erysipelatis*) to patients with sarcoma, and noted that there was a strong inflammatory reaction including hyperthermia that accompanied a reduction in tumor size (Coley, 1891, 1991; Nauts, 1976). Subsequently, Coley experimented with heat-killed bacterial extracts that were safer than live bacteria yet resulted in similar inflammatory and antitumor effects. The bacterial extracts were known as Coley's toxin and were included in early US Pharmacopeias for the treatment of cancer, and were marketed by the Park Davis company. The results achieved with Coley's toxin were considered variable by the cancer therapy community, which might have been due to variation in its manufacturing, and its use was discontinued in the 1960s when other chemotherapeutics became available. Coley's work is widely regarded as the origin of immunotherapy and immunooncology (IO).

Another immunostimulatory bacterium, Bacillus Calmette-Guerin (BCG), a mycobacterial strain derived from *Mycobacterium bovis* that was developed for vaccination against tuberculosis, has also found use as an anticancer immunotherapy agent (Fuge et al., 2015; Herr and Morales, 2008). Tuberculosis patients had been noted to have lower incidences of cancer as early as 1929 by Pearl. Studies by Old et al. (1959) and then Zbar et al. (1971) ultimately led to the recognition of BCG as an antitumor agent, and it became established as the standard of care therapy for superficial bladder cancer.

The number of bacteria being explored as tumor-targeting has been steadily growing, and collectively includes *Bifidobacterium*, *Caulobacter*, *Clostridium*, *Escherichia*, *Listeria*, *Proteus*, *Salmonella*, and *Streptococcus* (see Forbes, 2010; Zhou et al., 2018 for reviews). Continued investigations of the antitumor properties of these bacteria may prove that each have particular advantages in regard to safety and/or efficacy characteristics, or be of specific use against certain subtypes of cancer. In this discussion, some of the many studies with *Salmonella* are used to illustrate aspects of the technological approaches to developing microbes that target cancerous tumors and enhancing their anticancer activities.

Development of Tumor Targeted *Salmonella*

Early work on the use of *Salmonella* as a delivery vector for biologically functional proteins includes the study by Carrier et al. (1992) on oral and intravenous delivery of bacteria producing IL-1 β . IL-1 β biological activity was inferred by demonstrating that it induced radiation resistance in mice pretreated with the bacteria and then exposed to high doses of radiation. Use of *Salmonella* as an anticancer immunotherapy agents, either injected intralesionally or intraperitoneally, was also investigated and considered to be similar to BCG (Eisenstein et al., 1995). Subsequent work on the use of *Salmonella* as a cancer therapeutic agent utilized bacteria that produced a genetically engineered interleukin 2 (IL-2; Saltzman et al., 1996, 1997). Following oral or intraperitoneal delivery the bacteria colonized the liver and spleen. When hepatic tumors were implanted, the IL-2 producing bacteria localized in proximity to the tumors due to liver tropism, and resulted in an anti-tumor and anti-metastasis effects.

The approach for development of tumor-targeted *Salmonella* was based on intentionally delivering the bacteria systemically and assessing direct colonization of the tumor by harvesting the tumor and comparing it with normal tissues, such as the liver, thereby defining a tumor to normal tissue preference, or tumor-targeting ratio (Pawelek et al., 1995, 1997). The notion of using *Salmonella* or other microbes as direct tumor-cell targeting agents was inspired by the publication of Munzarova et al. (1992) who described the macrophage characteristics of melanoma. As a pathogen that specializes in invasion and survival within macrophages, *Salmonella* was speculated to potentially have innate tumor specificity. It was somewhat surprising when it was later revealed by electron microscopy that most of the bacteria were in the interstitial spaces of the tumor as well as inside phagocytic cells, with only a few intracellular bacteria within the melanoma cells (Pawelek et al., 1997). Although this initial result did not seem to support the original hypothesis of cell type specificity as a mechanism for tumor tropism toward macrophage-like tumor cells, it did suggested a complex interaction that might be mediated by extracellular bacteria combined with intracellular bacteria and possible

contributions from the immune system (Pawelek et al., 1997), concepts that have been bourn out by many times in subsequent studies (Zhou et al., 2018), and described further below. Later it was recognized that autophagy of *Salmonella* is involved in the antitumor mechanism (Lee et al., 2014), and that this may account for the absence of large amounts of intracellular bacteria within tumors.

The initial study of *Salmonella* tumor targeting utilized a hyperinvasive mutant, “clone 72” (Yale *Salmonella* clone 72; YS72), which had been selected for enhanced internalization into melanoma cells. Fortuitously, YS72 also a purine auxotroph due to the UV and nitrosoguanidine exposure used to generate the mutational pool of bacteria from which the hyperinvasive phenotype was selected (Pawelek et al., 1997). When injected systemically into mice with Cloudman S91 melanoma tumors, YS72 had an apparent tumor-homing ability, with a tumor targeting ratio greater than 1000:1 (Pawelek, Low and Bermudes, unpublished data). This ratio was a result of more than 10^9 colony forming units (CFU) per gram of tumor tissue after only 1 day, whereas only 10^6 bacteria had been injected into the mice, indicating that the result was due to selective replication within the tumor. And while the wild type *Salmonella* also preferentially replicated within tumors, indicating a natural tropism for tumors, its accumulation was to a lesser degree than clone 72, and rapidly caused death of the mice. Importantly, while the hyperinvasive clone 72 also had a slightly higher CFU within the tumor than wild type, it was approximately 10 times lower in the liver, and did not result in death of the immunocompetent mice, establishing that it was attenuated relative to the wild type strain. Melanoma tumor growth was delayed in the mice treated with clone 72 and their overall survival times increased, which was correlated with tumor growth delay. Thus, in mice, attenuated bacteria are safe, target tumors from a distant inoculation site, selectively replicate within tumors, and cause tumor suppression of tumor growth.

The results of these studies also established that attenuation could serve multiple purposes. As tumors are rich in purines due to their fast-growing nature as well as containing necrotic tissue due to irregular vasculature, purine auxotrophy provided both the safety necessary for administration to a live animal and a targeting enhancement mechanism, via a nutritional requirement, to increase specificity toward tumors. In addition, a third contribution of purine auxotrophy is competition of the bacteria with the tumor for available purines, and therefore also provides a mechanism to contribute toward tumor growth inhibition. Among the other features of these bacteria, it was also noted that *Salmonella* were facultatively anaerobic, as compared to the mostly anaerobic genus *Clostridium*, which could potentially provide an advantage for targeting smaller, more aerobic tumors. Furthermore, the pathogenic origin of the bacteria was thought to contribute to the general ability of the bacteria to temporarily evade the immune system to establish tumor colonization, although this ability is also shared with some non-pathogenic bacteria such as *Bifidobacterium*.

In subsequent, studies when partially immunodeficient mice were examined as the host for melanoma tumors, clone 72 was not sufficiently attenuated and resulted in death of the mice (Pawelek et al., 1997). Additional attenuating mutations that provided sufficient safety were added that included auxotrophy for isoleucine/valine, arginine, aromatic amino acids, and uracil. These strains retained both the tumor targeting properties and the antitumor effects of the clone 72 in immunodeficient mice. The suitability of these mutations was notable, as they further established the utility of mutations in biosynthetic pathways for the basic building blocks of amino acids and nucleotides for simultaneously providing attenuation and tumor selectivity while maintaining the bacteria's ability to delay tumor growth, similar to the results obtained with purine auxotrophy.

At the time of these initial studies, live attenuated vaccines, especially orally delivered *Salmonella* based vaccines, also provided a framework of both attenuation and protein delivery to draw from in order to develop tumor-targeted *Salmonella*. In fact, both purine auxotrophy (Bacon et al., 1950a,b, 1951) and aromatic amino acid auxotrophy (Hoiseth and Stocker, 1981) were known as attenuating mutations. A typhoidal strain, Ty21A, had been developed as a vaccine against typhoid fever that had multiple mutations including purine auxotrophy (Schödel, 1992). However, distinct differences in their effects on tumor-targeted bacteria were found among these known attenuating mutations. For example, aromatic amino acid auxotrophy was compatible with tumor targeting and antitumor activity (Pawelek et al., 1997), but while *purI* mutations were compatible with both large and small tumors (Pawelek et al., 1995, 1997; Low et al., 1999), *purA* mutations only worked with very large tumors (Bermudes, unpublished). In addition, other attenuated genetic backgrounds that seemed particularly useful for vaccines, such as PhoP/Q mutations (Hohmann et al., 1996), resulted in bacteria that targeted tumors but lack significant antitumor activity (John Pawelek, Brooks Low, David Bermudes and Sean Murray, unpublished observations).

The initial study of *Salmonella* tumor targeting also explored the potential of the bacteria to delivery a heterologous enzyme, the herpes simplex thymidine kinase (HSVTK). HSVTK is known as a prodrug-converting enzyme because it has the ability to activate a non-toxic prodrug (acyclovir or gancyclovir) into its active phosphorylated form that has the ability to inhibit DNA synthesis and cause cell death (Pawelek et al., 1995, 1997). The HSVTK was constructed with a Type II bacterial secretion signal to export the HSVTK into the periplasm, and was demonstrated to be enzymatically active. When melanoma-bearing mice were administered these bacteria, there was a gancyclovir-dependent enhancement of antitumor activity, resulting in the proof of concept that genetically engineered *Salmonella* could selectively deliver an enzymatically active therapeutic protein directly to the tumor and activate an anticancer drug.

Salmonella is a gram-negative bacterium with a typical lipid A in the outer leaflet of the outer membrane. Lipid A is a pathogen associated molecular pattern (PAMP) that is recognized by Toll-like receptor 4, and through signal transduction results in production of TNF α by monocytes and macrophages. As with most gram-negative bacteria, excessive exposure to lipid A via bacteremia results in TNF α -mediated septic shock in the host, which is often lethal. However, a notable exception occurs in mice (Keith Joiner, personal communication; Fink, 2014). Even normally responsive mice have a lethal dose of LPS that is substantially less than the toxic does in normal human volunteers. For example, the LD₅₀ dose of LPS in mice can be 10 to 1000-fold or more

greater than the dose of LPS that is required to induce acute illness in humans (Taveira da Silva et al., 1993). Thus, the potential for use of a tumor-targeted *Salmonella* that functions safely in mice could be severely limited by toxicity in humans.

Several potential solutions to the lipid A mediated septic shock problem were investigated. Earlier studies of lipid mutant bacteria had shown that not all forms of lipid A were equally stimulatory of TNF α . Examples included monophosphoryl lipid A and lipid X, which both occur in the deep rough mutant *Salmonella minnesota* R595 (Danner et al., 1987), and have even been shown to prevent induction of septic shock. However, it was found that this strain of *Salmonella* does not inhibit tumor growth (Bermudes unpublished observations). Other mutants that were assessed included *firA*, which had some tolerance to physiological temperature and was of low pyrogenicity, but only colonized tumors at a rate of about 1000-fold less than other mutants (Pawelek et al., 1995). Generally, among the other lipid mutants, the attendant problem is that they result in a temperature sensitive phenotype, whereas the requirement for a tumor-targeted vector is to be functional at physiological temperature.

A series of investigations on temperature sensitive mutants and their suppressor mutations led to the publication of the first non-temperature sensitive lipid mutant in *E. coli* (Somerville et al., 1996), which had a deletion in the *msbB* gene that is responsible for myristolation of lipid A (Clementz et al., 1997). Deletion of *msbB* in *Salmonella* also retained low pyrogenicity in monocyte assays of TNF α production, approximately 10,000 times lower than induced by wildtype, but retained the ability to grow at physiological temperatures (Bermudes and Low, 1997; Khan et al., 1998; Low et al., 1999). When *msbB* mutants were assessed in murine tumor models, tumor targeting and antitumor activity were both retained (Bermudes and Low, 1997; Low et al., 1999). Faster growing variants of *msbB Salmonella* were isolated which proved to be suppressor mutations for other physiological sensitivities that were induced by the *msbB* mutation (Low et al., 2016), including sensitivity to salt (Murray et al., 2001), chelating agents and MacConkey media containing bile and crystal violet (Murray et al., 2004), polymyxin (Murray et al., 2007) and CO₂ (Karsten et al., 2009).

Although mice are relatively insensitive to TNF α mediated septic shock, the *msbB* bacteria were found to be highly attenuated, and generally safe without additional attenuating mutations. This was somewhat surprising considering that the lipid A did not have toxic consequence for the mice. The primary reason for this difference appears to be due to enhanced ability of macrophages to eliminate these bacteria. Interestingly, *msbB Salmonella* retained a tumor targeting ratio of greater than 1000:1 despite the enormous alteration in the ability to be eliminated from normal tissues. Furthermore, without an auxotrophic mutation generating a requirement for nutrients within the tumor, tumors remained the site of preferential replication. These data were interpreted as indicating the tumor targeting phenomenon (preferential replication) within tumors might also involved the immune privileged nature of the tumors (Low et al., 1999), and that forms of attenuation other than auxotrophy were compatible with the tumor targeting system, and in fact, offered an alternative to requiring a metabolite provided by the tumor in order to enhance the tumor targeting ratio.

The proof of concept that the *msbB* mutation would provide safety against septic shock for non-murine animals was demonstrated in Sinclair swine (Low et al., 1999). At a high dose (10⁹ CFU), 9 of 10 swine died within five days, whereas all of the *msbB*-treated swine survived. Purified LPS from *msbB Salmonella* injected into swine resulted significantly lower respiration rates compared to injection of wild type LPS, consistent with the cellular assays described above. Collectively, both the lipid A and the whole bacteria were significantly reduced in their inflammatory properties, and significantly reduced in virulence.

The development of the *msbB Salmonella* was widely viewed as an advancement that could facilitate human clinical studies (Less Shocking Antitumor Agents?, Marshall, 1999), and several human clinical trials were subsequently sponsored by Vion Pharmaceuticals in New Haven, CT. Although there had been earlier investigations of *Clostridium* in humans for the treatment of cancer, there had never been a review by the Food and Drug Administration (FDA) of any of the prior studies of intravenously injected bacteria, which had all been Gram-positive. Thus, intravenous injection of live Gram-negative *Salmonella* faced significant scrutiny in order to allow the studies to be initiated. However, it was subsequently shown in two separate publications that live bacteria can be subjected to many of the same principles as chemical entities, biologics and orally delivered bacterial vaccines, which helped guide the regulation of this precedent of a live intravenously administered bacterium (Clairmont et al., 2000; Lee et al., 2000; Lee, 2002).

VNP20009, an *msbB* strain of *Salmonella* derived from clone 72 that was a Tn10 derived purine auxotrophy combined with hyperinvasiveness and was antibiotic sensitive (later described by Low et al., 2004), was used for the clinical studies. VNP20009 also contains a large deletion that acts as a suppressor for salt and EGTA sensitivity referred to as the Suwwan mutation (Murray et al., 2004; Broadway et al., 2014). VNP20009 was evaluated in mice, dogs and monkeys for its biodistribution properties and safety (Clairmont et al., 2000; Lee et al., 2000). It was estimated that VNP20009 is approximately 50,000 times less toxic than the wildtype *Salmonella enterica* serotype Typhimurium.

Salmonella Intratumoral Administration in Humans

VNP20009 underwent its first human clinical study at the Cleveland Clinic, administered by direct intra-tumoral (IT) injection (Mier et al., 2001). The results of this study are of significance in contrasting the differences observed in mice and human treated with VNP20009, and have provided some guidance for the development of new vectors with improved properties. Nine patients were enrolled representing melanoma (4), renal (3), prostate (1) and merkel cell (1) tumors. After 12-19 days following intratumor injection (conducted as a dose escalation with different patients) excisional biopsies or fine needle aspirates (FNA) were performed and assessed for CFU/g tumor tissue. The bacteria were found in 6 of 9 patients of these tumors, with 10⁶ CFU/g as the highest-level colonization within the study (compared with 10⁹ CFU/g in mice), which was therefore substantially lower than was observed in preclinical models. Inflammation, necrosis and fibrosis were observed in most patients, with most patients being stable at 30-days

follow-up, although two of the tumors grew more rapidly directly following injection. No toxicities were reported. Three of the observations from this study were of particular interest: (1) the bacteria were shown to be safe, (2) the bacteria persisted in tumors at least 12 days in most of the tumors injected and (3) the CFU/g tumor tissue was substantially lower in humans than in mice.

Salmonella Intravenous Administration in Humans

The second clinical study of VNP20009, which reported the results of intravenous (IV) administration, was conducted at the National Cancer Institute, primarily (24/25) on melanoma patients that were no longer responsive to chemotherapy or immunotherapy (Toso et al., 2002). These results have significantly shaped the on-going development of *Salmonella*-based vectors in terms of establishing differences in VNP20009's translation from mice to humans, and have helped define many of the goals of on-going research.

The study was conducted as a bolus intravenous administration, dose escalation, with evaluation of toxicities, tumor colonization (CFU/g) and possible antitumor effects. The dose began at 1×10^6 CFU/m² and was escalated as a semi-log function, with a total of seven different dose levels administered. The study established that 3×10^8 CFU/m² was the maximum tolerated dose; four patients were administered one dose higher (1×10^9 CFU/m²), which resulted in unacceptable toxicities consistent with disseminated bacteremia. Of the 25 patients administered in the seven dose escalations, only 7 received the maximum tolerated dose (MTD) or higher. Of note in the study was the overall tolerability of VNP20009, which reached up to 200,000 CFU/ml of blood at the MTD. At the MTD, only 1 of 3 patients was documented to have bacteria localized within their tumors. The presence of the bacteria in that patient went undetected by fine needle aspiration (FNA), but was later established by excisional biopsy as 1×10^4 CFU/g; a finding of CFU/g of tissue similar to the intra-tumoral study in humans and substantially lower than occurred in mice. The variation from undetected by FNA to detectable by excisional biopsy was also of significance, as it suggested that the distribution within tumors is heterogeneous, and likely occur as small foci. This is also consistent with the finding that the initial entrapment of the bacteria within tumors is sparse (Forbes et al., 2003). In the cohort that received the highest dose (1×10^9 CFU/m²), two patients were documented to have bacteria in their tumors by FNA; one with 2×10^2 CFU/g and one that progressed to levels 7×10^9 CFU/g. Overall, the findings showed that VNP20009 was had acceptable toxicity, and targeted tumors in 1/3 patients at the MTD, and that the CFU/g was substantially lower compared to mice. The only high-level tumor targeting with CFU/g equivalent to that observed in mice occurred in humans who had received a dose above the MTD.

Other finding of the intravenous study included cytokine analysis, with IL-1 β , TNF α , IL6, and IL12, results that are consistent with the immunooncology effects of bacteria. However, no objective clinical responses were found in the study, even in patients that were documented to have had bacteria that colonized their tumors.

Salmonella Continuous Intravenous Infusion in Humans

The mode of drug delivery is known to have the potential to alter the distribution, and therefore a 4-hour continuous infusion of VNP20009 was studied in four patients with metastatic melanoma, with tumor colonization measured exclusively by excisional biopsy within two weeks of administration (Heimann and Rosenberg, 2003). However, only one patient was found to be positive for tumor colonization, with only 58 CFU/g tumor tissue, with no objective antitumor responses.

Intratumoral Administration of Salmonella Expressing Cytosine Deaminase in Humans

Following the intravenous clinical trials of VNP20009, evaluation of a derivative of VNP20009 engineered to express the *E. coli* cytosine deaminase (King et al., 2002, 2009) was initiated in head and neck tumor patients (Cunningham and Nemunaitis, 2001). The *E. coli* cytosine deaminase acts as a prodrug-converting enzyme that converts the non-toxic 5-fluorocytosine (5-FC) to the known cytotoxic anti-cancer metabolite 5-fluorouracil (5-FU). Thus, by virtue of the bacterial selective localization within tumors, the non-toxic prodrug could be preferentially activated within tumors and therefore selectively toxic toward tumors. The study, which was reported after treating only three patients (Nemunaitis et al., 2003), escalated intratumoral doses beginning at 3×10^6 /m², ending in 3×10^7 /m². The patients also received six cycles of 5-FC. The results indicated that two of the three patients had their tumors colonized by the bacteria, which persisted for at least 15 days, ranging from 84 to 2.6×10^6 CFU/g tumor tissue. There was a measurable difference in the blood to tumor ratio for the metabolite 5FU, which coincided with the colonized tumors and not the un-colonized tumor. This study established for the first time the *in vivo* conversion of a prodrug by an intratumoral bacterium. The patient with the higher level of bacteria had evidence of stabilized disease in the injected tumor, while disease progression occurred in the uninjected tumors. The study represented an important proof of concept for bacterial colonization by intratumoral injection and activation of a cytotoxic agent. However, due to financial constraints, Vion Pharmaceuticals discontinued funding the study.

Summary of the Salmonella Clinical Studies in Humans

Intravenous (IV) and intratumoral (IT) administration of the live VNP20009 bacteria to humans was generally well tolerated, and a maximum tolerated dose of the bacteria was established for IV administration. In the IT study, the bacteria were documented to persist for 12 days or longer. In the IV study at the MTD, the bacteria targeted the tumors in one of three patients, and no tumors were documented to have been targeted below the MTD. FNA was shown to be inaccurate in assessing tumor colonization, and

suggests that the distribution of the bacteria within the tumors is heterogeneous. The percentage of tumors targeted by the bacteria following IV administration in humans was substantially lower than in preclinical models. In the intratumoral and intravenous administration studies, the CFU/g of tumor tissue was also usually lower than in preclinical models. Continuous infusion did not improve the targeting percentage or CFU/g tumor tissue. In these studies, no objective antitumor responses were observed. TAPET-CD was administered to three patients by intratumoral administration. Two of the patients treated with TAPET-CD were documented to have tumor colonization and conversion of 5FC to 5FU, and one patient had evidence of stable disease in the injected tumor. Overall, these findings suggest that improvements in (1) the percentage of tumors colonized, (2) the number of CFU/g of tumor tissue, and (3) the antitumor effects of the bacteria, represent areas that could lead to development of more effective live tumor targeting *Salmonella* vectors. In addition, murine tumor models that give results similar to those from the human studies with lower percentages of tumors targeted, and with lower CFU/g tumor tissue would aid in assessing the effects of efforts to improve the *Salmonella* tumor-targeting properties.

Salmonella Veterinary Clinical Trials for the Treatment of Cancer

VNP20009 was assessed in veterinary trials of pet dogs with naturally occurring tumors. VNP20009 was administered to forty-one dogs with a range of different tumor types where there was no established standard therapy, or had failed or declined standard therapy in a Phase I study (Thamm et al., 2005). The study included excisional biopsies to assess tumor colonization and monitoring of clinical signs to determine the maximum tolerate dose (MTD). Bacteria were detected from 42% of the tumors. Of 35 evaluable patients, there were 4 complete responses and 2 partial responses, and stable disease lasting at least 6 weeks occurred in 10%, with overall response rate of 15%. Although these results were encouraging, there has been no follow-up study with VNP20009. Other studies of live bacteria for the treatment of canine cancer have included *Clostridium* (Roberts et al., 2014) and a *Salmonella* expressing IL-2, described below.

An IL2-expressing *Salmonella* was recently evaluated in a Phase I study in pet dogs with osteosarcoma (Fritz et al., 2016). Dogs were treated on day 0, followed by amputation of the affected bone at day 10, with concurrent chemotherapy. The IL2 expressing *Salmonella*-treated dogs had extended disease-free interval (DFI) compared to those not receiving the bacteria. Overall the treatment was well tolerated and supports the potential for *Salmonella* expressing IL2 as an adjuvant therapy for dogs with osteosarcoma.

In addition to the potential of these canine studies to result in significant antitumor effects in dogs, they also point out that, at least to date, the murine studies are more similar to those in dogs than they have been in humans. However, as also noted, the human clinical studies were primarily limited to pretreated melanoma patients, whereas the canine studies did not all receive pretreatment and included melanoma as well as several other types of tumors, with complete responses in two with metastatic melanoma, one with soft tissue sarcoma, and one with cutaneous epitheliotropic lymphoma. Therefore, additional studies are needed to further correlate murine studies with those of dogs and humans.

Mechanisms of Salmonella Antitumor Effects

Multiple mechanisms associated with *Salmonella* antitumor effects have been described, most of which involve immune responses stimulated by the bacteria. Other mechanisms involve *Salmonella*-induced apoptosis through type III secretion and through autophagy.

Antitumor Effects of Tumor-Targeted Salmonella

Tumor necrosis factor alpha (TNF α), formerly known as cachectin, was discovered as the antitumor cytokine that is elicited by bacterial lipopolysaccharide (LPS; Beutler and Cerami, 1989), work that was inspired by the findings of William B Coley. LPS is detected by macrophages and dendritic cells through CD14 and TLR4 receptors whose signal is transduced through MyD88 (Medvedev et al., 2002). TNF α elicited by *Salmonella* through TLR4 has been shown to participate in the *Salmonella* antitumor effect (Lee et al., 2008) and to result in a hemorrhagic effect with marked disruption of the tumor vasculature (Leschner et al., 2009), although this effect is exhaustible in experimental models (Kocijancic et al., 2017).

Tumor associated macrophages (TAMS) and similar M2-like macrophages produce the immunosuppressive cytokine IL10 (see Chávez-Galán et al., 2015 for a review), and have reduced iNOS and TNF α expression and collectively limit antitumor immune responses. TLR4 (Lee et al., 2008) and MyD88-TLR (Kaimala et al., 2014) are required for a *Salmonella*-induced antitumor responses, and result in increased iNOS, IFN γ and S100A9 that have antitumor effects, with reduced ARG1, IL4 TGF β and VEGF that would otherwise promote tumor growth. The presence of *Salmonella* within tumors has the outcome of shifting macrophages to an M1-like phenotype, altering TAMS away from their suppressive state. The presence of *Salmonella* also results in the conversion of immunosuppressive myeloid-derived suppressor cells (MDSCs) into TNF- α producing myeloid cells (Hong et al., 2013). *Salmonella*, but not *E. coli*, induce IPAF, NLRP3 and P2X7 and secretion of IL-1 β in response to LPS and damaged cancer cells (Phan et al., 2015).

Macrophage phagocytosis of bacteria results in MHC Class II antigen processing, which induces CD4+ T-cells to stimulate B-cells to produce antibodies. B-cells contribute to the tumor-targeting, or selective tumoral replication effect through production of

antibodies, resulting in limiting *Salmonella* within normal tissues (Lee et al., 2011b). Proliferation within tumors may be due to the poor penetration of antibodies within tumors as well as other immune components that would otherwise control *Salmonella* replication. This differential effect thereby contributes to the apparent tumor targeting that is the result of preferential growth within the tumor compared to normal tissues. Macrophages may also produce nitric oxide (NO) in response to *Salmonella* that has an antitumor effect that can be enhanced by deletion of the *Salmonella* genes involved in NO detoxification (Barak et al., 2010).

The presence of bacteria within tumor cells also results in cytotoxic T-cell responses from *Salmonella* (Avogadri et al., 2005; Saltzman, 2005; Lee et al., 2011a), which is believed to contribute to through immunogenic cell death (Kroemer et al., 2013; Galluzzi et al., 2016). The presence of intracellular bacteria or cytoplasmic introduction of proteins through secretion of Type III effector systems effectively targets the cells for elimination by cytotoxic T-cells through MHC Class I antigen presentation. The presence of *Salmonella* inhibits indoleamine 2, 3-dioxygenase 1 (IDO) expression (Kuan and Lee, 2015; Lin et al., 2017) and increases the T cell-dependent immune response.

The presence of the bacteria results in upregulation of connexin 43 which also inhibits IDO (Lin et al., 2017) and increases gap junctions that promote tumor antigen presentation through adjacent dendritic cells and results in activation of cytotoxic CD8 + T-cells (Saccheri et al., 2010). Bacterial upregulation of connexin 43 has also been found to suppress tumor angiogenesis through hypoxic-induced factor-1 α mediated downregulation of VEGF (Wang et al., 2015), and also inhibits phospho-protein kinase B (AKT)/phospho-mammalian target of rapamycin (P-mTOR; Tu et al., 2016). Increased gap junctions also increase sensitivity to chemotherapeutics (Chang et al., 2013), and the Type III effector protein SipA downregulates the P-glycoprotein multidrug resistance pump, and also increases cancer cell sensitivity to chemotherapeutics (Mercado-Lubo et al., 2016). *Salmonella* treatment also results in quiescent tumor cells altering their cell cycle status, and become sensitive to chemotherapeutics (Yano et al., 2014).

Bacterial flagellin is a potent TLR5 agonist whose activation by bacteria is associated with tumor cell growth delay (Sfondrini et al., 2006; Cai et al., 2011), enhanced CD8 + T cells (Nguyen et al., 2013), a perforin-dependent response against tumor cells by natural killer (NK) cells (Leigh et al., 2014), and IFN- γ release mediated by the inflammasome intracellular danger sensor NLRC4 (Kupz et al., 2014). *Salmonella*, but not *E. coli*, induce an inflammasome response through secretion of IL-1 β in response to LPS and damaged cancer cells (Kim et al., 2015; Phan et al., 2015). NK1.1 + CD3- cells have also been associated with *Salmonella*-induced antitumor effects (Feltis et al., 2002).

Autophagy also plays a role in inhibiting the antitumor effect of bacteria. A blockade of autophagy using siRNA has shown enhanced tumor targeting and cancer-cell killing (Liu et al., 2016). Blocking autophagy using chloroquine through increasing bacterial targeting also enhances the antitumor effect of the bacteria and promoting immune infiltrates into the tumor (Zhang et al., 2016b).

Salmonella are known to be able to directly induce apoptosis of macrophages (Gálan et al., 2014; Monack et al., 1996), and there is evidence for direct apoptosis induction of tumor cells (Jia et al., 2007; Li et al., 2012; Uchugonova et al., 2015; Mercado-Lubo et al., 2016). Necrosis and cell lysis varies among different cell lines exposed to *Salmonella* A1-R (Uchugonova et al., 2015) indicating that cancers are not uniform in their response to the effects of *Salmonella*.

Improved *Salmonella* Genetic Backgrounds Tumor Models and Assessments of Antitumor Effects

Stemming from the human clinical trials demonstrating safety and tumor targeting in some humans, areas for potential improvement and augmentation have become a focus of many recent and on-going studies. Owing to lack of antitumor activity in humans, lower percentage of tumors targeted, and generally lower CFU/g, there have been many different approaches aimed at improving on these results as well as new applications that utilize tumor-targeting *Salmonella*. A few of the many studies are described below.

Improved Murine Tumor Models

A murine model that yields results with VNP20009 or other *Salmonella* similar to those obtained in human studies might represent an improved model. Recently it was shown that VNP20009 had 4-logs less innate tumor targeting in autochthonous BALB-neuT tumors compared to the conventional murine breast tumor model 4T1 (Drees et al., 2015). This finding could indicate that these tumors more closely match the physiology of human tumors in regard to their permissiveness to initial entrapment and subsequent bacterial replication properties (Lezzi et al., 2012). Thus, this could be correlated with the lower colonization rates and lower CFU/g tumor results of the intravenously administered VNP20009 in humans. Intriguingly, pre-treatment with the vascular disrupting agent combretastatin A-4 significantly increased the presence of the bacteria 2-days post treatment. These findings suggest autochthonous tumor models combined with vascular targeting agents may facilitate translational studies of tumor-targeting bacteria.

Mutational Backgrounds

Different mutational backgrounds are thought to hold the potential to improve the tumor-targeting and antitumor effects of attenuated *Salmonella*. Several different mutational backgrounds are currently being explored in preclinical models, and may represent improvements that can be translated from mice to humans. *Salmonella* strain A1-R, which is a leucine and arginine auxotroph that was selected by reisolating the bacteria directly from murine tumors, has shown strong antitumor activity with complete regressions in multiple tumor models (Zhao et al., 2006, 2007), and has shown advantages in antitumor effects over

VNP20009 (Zhang et al., 2017). Another strain of *Salmonella* that is currently being evaluated has a mutation guanosine pentaphosphate (ppGpp) synthesis, and has recently been shown to be highly attenuated and effective as an anti-tumor vector (Yun et al., 2012). Reduced toxicity may lead to the ability to deliver higher doses that may improve the tumor targeting percentage and/or the CFU/g tumor tissue.

Isolation and identification of mutations that enhance tumor tissue levels and decrease normal tissue levels has also been explored (Arrach et al., 2010). Mutation in *STM3120* were identified as avirulent and improved compared to a parental *aroA/aroD* *Salmonella* in their ability to target tumors. In another study (Zhang et al., 2016a) however, *STM3120* was identified as a key factor contributing to the antitumor effect of VNP20009 in melanoma along with *slyA* and *htrA*, underscoring that mutations affecting virulence may sometimes interfere with antitumor effects. Mice treated with *Salmonella* containing these mutations had reduced proinflammatory cytokines TNF α and IL-1 β that associated with antitumor effects, and thus it is believed these genes contribute to the immune-oncology effects of *Salmonella*.

Salmonella with a mutation in the ZnuABD transporter has also been studied for its antitumor properties (Chirullo et al., 2015). These bacteria replicate in mammary adenocarcinomas, delay tumor growth and increase survival. These bacteria also retain their ability to cause an inflammatory response that includes recruiting innate and adaptive immune cells to the tumor.

Modulating Bacterial Entry Into Tumors

Penetration of drugs into tumors has long been understood as a limitation of cancer chemotherapeutics (Jain, 1994), and is the subject of active investigation. Decreased initial entry of bacteria into tumors, which is already low in mice (Forbes et al., 2003), would be consistent with the observed differences in tumor targeting between studies in murine tumor models and the human clinical studies. Initial entry of the bacteria into tumors has been modulated using several different approaches.

Pretreatment with TNF α (Sheppard et al., 1989) or by endotoxin-induced release of TNF α (Bloksma et al., 1982) can result in tolerance (tachyphylaxis) to the potentially lethal effects of TNF α , and thus pretreatment could enhance both efficacy and safety. The potential for pretreatment with lipid A as a modulator of tumor penetration has been investigated (Zhang et al., 2014). Because treatment with *Salmonella* results in TNF- α mediated vascular hemorrhage (Leschner et al., 2009), lipid A pretreatment may also increase influx into the tumor mediated by TNF- α . Pretreatment with lipid A resulted in a measurable increase in the fraction of well-colonized tissues (>25%) within a mouse model of breast cancer. Primer dosing of *Salmonella* has also been used to enhance efficacy (Tome et al., 2013). Following an initial low dose, a second dose ten times higher was given four hours later, and resulted in increased TNF α , enhanced destruction of tumor vasculature and smaller Lewis lung tumors compared to the high dose only.

The investigational agent PEGPH20 is a long-circulating (pegylated) hyaluronidase that increases blood flow into tumors that have elevated interstitial fluid pressures (IFP) and vascular collapse due to the presence of extracellular hyaluronan (Yu and Tannock, 2012; Provenzano et al., 2012). Pretreatment of autochthonous and orthotopic pancreatic tumors in mice with PEGPH20 depleted extracellular matrix hyaluronan, resulted in significantly higher levels of *Salmonella* colony forming units within the tumors, and resulted in complete regressions in combination with an IDO shRNA (Manuel et al., 2015).

Cell-Surface Binding Ligands and Antibodies

Bacterial expression of antibodies on the cell surface increases tumor targeting and efficacy. Surface display of an anti CEA-specific antibody enhanced the antitumor activity of VNP20009 against a MC38 murine adenocarcinoma transduced with CEA (Bereta et al., 2007). Similarly, surface expression of an anti-CD20 antibody results in significantly enhanced cell binding to CD20-positive cells (Massa et al., 2013). Coexpression with the prodrug converting enzyme herpes simplex virus thymidine kinase (HSVTK), which activated ganciclovir and conferred ganciclovir sensitivity in combination therapy against CD20 human xenografts, resulted in complete eradication of the implanted lymphomas. This approach therefore represents a favorable combination for using *Salmonella* engineered to include both increased targeting and a controlled cytotoxicity mechanism.

Bacterial cell-surface display of a ligand (RDG) for tumor associated $\alpha v \beta 3$ integrin over-expressing cancer cells has utilized to enhance tumor accumulation compared to the parental *Salmonella* strain (Park et al., 2016). The strain is improved in both *in vitro* binding to cancer cells and *in vivo* initial and longer-term targeting levels with up to a 1000-fold increase in solid tumors, which correlated with improved antitumor efficacy.

Modulation of Motility and Chemotaxis

The potential for motility to play a positive role in *Salmonella* antitumor effects and targeting ability was suggested early in their development (Bermudes et al., 2001). Modulation of motility and chemotaxis have been explored in regard to tumor accumulation and antitumor activity in several different tumor models. Collectively, the results support a role for motility and chemotaxis shaping the biodistribution within the tumor, especially with respect to location near blood vessels and quiescent cells. However, the bulk of the tumor entry and CFU/g tumor tissue within murine tumor models apparently does not require motility or chemotaxis. For example, Stritzker et al. (2010) found that chemotaxis and flagellar mutants did not alter the apparent tumor biodistribution as assessed by fluorescent microscopy, and *cheY* (chemotaxis⁻) and *fliGHI* (motility⁻ and chemotaxis⁺) mutations in *Salmonella* SL1344 did not numerically alter tumor or liver CFU/g or the apparent biodistribution as assessed by fluorescent microscopy for either chemotaxis⁻ or motility⁻ mutants.

VNP20009 is deficient in chemotaxis, containing a P110S mutation in *cheY*, a key response regulator involved in flagellar motility that was not recognized at the time of the human clinical study (Broadway et al., 2014, 2015). The *cheY* mutation can be suppressed by mutations in *fliM*, whose gene product is known to interact with CheY (Broadway et al., 2017). Restoring the wild type CheY amino acid sequence partially restores chemotaxis in VNP20009. However, the CheY⁺ VNP20009 did not accumulate in tumors at higher levels, and neither the CheY⁺ VNP20009 nor VNP20009 had significant antitumor properties against the murine 4T1 breast cancer primary tumors, or on the formation of metastases. Both the parental and CheY⁺ strain had significant liver toxicity in this model (Coutermarsh-Ott et al., 2017). Although this study also did not find significant improvement in tumor colonization by VNP20009 CheY⁺, it did find an improvement in the targeting ratio, with slightly lower levels in normal tissue.

Despite the apparent lack of influence on the bulk biodistribution of *Salmonella* within tumors, it is of potential importance to note that *Salmonella* chemotax toward larger cylindroids that contain quiescent cells as compared to smaller cylindroids that lack them (Kasinskas and Forbes, 2006) and is increased in ribose receptor deficient *Salmonella* (Kasinskas and Forbes, 2007). Because quiescent cells are more difficult to treat therapeutically than actively growing cells, this observation provides a potential mechanism for improved treatment against this tumor cell subpopulation by using tumor-targeted bacteria that switch quiescent cells from G0/G1 to S/G2/M and makes them sensitive to chemotherapeutics (Yano et al., 2014). Therefore *Salmonella* combinations with standard chemotherapies may offer the potential to treat quiescent tumor cells that could otherwise persist and result in subsequent tumor regrowth.

Improved *Salmonella* Gene Expression and Antitumor Efficacy

Improved tumor-targeting properties, as described above, may enhance the colonization efficiency in terms of the percentage of tumors colonized, the maximum CFU within tumors, and the tumor-targeting ratio. However, in an effort to augment or surpass the innate antitumor effects of bacteria, a variety of different approaches have been taken to develop antitumor effector systems. These systems generally involve the combination of one or more effector proteins, a gene expression cassette, and a diffusion, secretion or release systems for the effector component that delivers it outside of the bacteria.

Antitumor Effector Systems

A variety of systems have been explored as antitumor effectors for expression by tumor targeted bacteria. These systems fall within several broader categories as listed below and in Table 1.

Prodrug converting enzymes metabolize non-toxic precursors into toxic metabolites that have effects at the site of conversion. Localization of a prodrug converting enzyme to a specific site results in localized conversion with higher concentration at that site, and has been explored widely as a form of anticancer therapy (Lehouritis et al., 2013).

Cytokines are immune signaling molecules with the potential to recruit an immune response against the cancerous tissue. Cytokines have been studied intensively as cancer therapeutics (Lee and Margolin, 2011).

siRNA Delivery. Small interfering RNA (siRNA) delivery makes use of *Bactofection*, the transfer of DNA from a bacterium to a eukaryotic cell. Transfer of DNA with eukaryotic promoters results in RNA and/or protein expression by the eukaryotic cell (Pálffy et al., 2006; Chung et al., 2015).

Antivascular/antiangiogenic factors block neovascularization, which is required for tumor growth, and therefore inhibit tumor growth (Vasudev and Reynolds, 2014).

Cytotoxic proteins directly result in tumor cell death. Proteins secreted by bacteria have the potential to result in a “bystander” effect, whereby cells only adjacent to the site of production are also killed.

Protease Inhibitors halt the action of proteases, which are abundant in tumors and are involved in tumor metastasis and degradation of protein-based therapeutics. In the context of delivery by tumor-targeted bacteria, they have the ability to halt proteolytic activity, thereby enhancing the activity of proteins therapeutics delivered by the bacteria or administered independently, as well as inhibiting metastasis (Quintero et al., 2018).

Apoptosis inducing peptides are not directly toxic, but activate the cellular system for self-destruction, and can result in death of tumor cells.

Immune activator peptides have immunostimulatory effects that activate and/or recruit immune cells to the site of cancerous tissues and result in anticancer effects.

Enhanced nitric oxide production is an approach that uses the anaerobic respiration of *Salmonella* to produce NO, combined with deletion of the genes encoding nitric oxide detoxification proteins. NO is associated with anticancer effects, although its mechanism is not clearly defined.

Bacterial Cell Lysis and Inducible Delivery

Bacterial delivery systems have been engineered using phage and colicin lysis proteins, and cell wall biosynthesis mutations to generate empty immunogenic shells in order to release internal contents or preferentially release periplasmic contents. Lysis of

bacterial host cells by bacteriophage Φ X174 is controlled by the phage-encoded lysis protein E (Henrich et al., 1982; Young and Young, 1982). Lysis protein E is used as a biotechnological tool to generate non-replication competent bacterial-based vaccines with nearly intact antigenic bacterial cell walls that lack cytoplasmic contents, known as bacterial ghosts (Langemann et al., 2010). Programmed loss of bacterial cell wall structural integrity can also be achieved in live replication competent vaccines by disruption of the *asd* gene, which is essential for cell wall peptidoglycan synthesis (Kong et al., 2008). Through utilization of arabinose inducible control (Loessner et al., 2007) to keep the gene on, cell lysis occurs in the absence of the inducer. Programmed lysis can be further enhanced by arabinose control of the cell wall biosynthesis genes *murA* and *asd* coupled with expression of the p22 phage c2 gene (Kong et al., 2012). Subsequent to removal of the arabinose inducer caused by introduction of the bacteria into an arabinose-free host, *murA* and *asd* are further inhibited through loss of repression of P_R , which then drives an antisense *murA* and *asd*. The combined result of this two fold control of *murA* and *asd* is not only highly efficient at release of an antigenic payload, but also results in complete loss of viability, and thereby provides biological containment.

High lysis efficiencies can also be engineered using the bacteriophage lambda lysis gene cluster SRRz for tumor-targeted delivery with anhydrotetracycline induction coupled in parallel with salicylate induction for therapeutic gene expression has also been further provided (Camacho et al., 2016). This study further combined the system with a *sifA* mutation that results in liberating the bacteria from their location within host cell vacuoles into the host cytoplasm. Efficiency of bacterial autolysis systems continues to be improved for biological delivery by combinations such as inclusion of the λ phage holin-endolysin with the Φ X174 gene E (Won et al., 2017). Selective release of periplasmic proteins has also been accomplished by use of bacteriocin release proteins (BRPs; Van der Wal et al., 1995). The colicin E3 lysis protein has been used to enhance release of a tumor-selective toxin based on *Pseudomonas* ToxA (Quintero et al., 2016).

Quorum Sensing Regulated Gene Expression Circuits

The application of synthetic biology and artificial gene circuits is being applied to bacterial delivery systems (Prindle et al., 2012). Quorum sensing is a gene expression system based on concentration-dependent induction by an autoinducer produced by the bacteria. When concentrations of the inducer are high, indirectly due to high concentrations of the bacteria, the inducer interacts with the quorum gene expression regulon to initiate expression. Because bacteria such as *Salmonella* localize within tumors to numbers exceeding 10^9 CFU/g, the preferential localization of the bacteria offers a tissue-dependent bacterial concentration phenomena that can be coupled to a quorum sensing circuit. Bacterial quorum sensing circuits have been reengineered to control bacterial invasion of host cells (Anderson et al., 2006). An *E. coli* modified to express the *Yersinia* invasion gene under inducible control of the *Vibrio fischeri* quorum sensing *lux* operon was used to induce uptake of non-invasive *E. coli*, which they further tuned using a ribosomal binding site library, and showed that concentration dependent invasion occurred based on quorum-based induction (Anderson et al., 2006). Quorum sensing has also been used induce tumor-localized expression (Swofford et al., 2015; Din et al., 2016), and synchronized tumor-localized lysis combined with expression (Din et al., 2016). The *Vibrio fischeri* quorum sensing *lux* operon was used to preferentially expressing a GFP reporter within murine tumors (Swofford et al., 2015). Above a high-level threshold (4.2×10^{10} CFU/g), expression was triggered to the same levels as constitutive controls, while below 0.6×10^{10} , expression levels were only at 3%. The colonization level within liver of these bacterially infected mice was completely below the level required to initiate expression, thereby preventing liver-associated expression and establishing that expression is tumor-selective. Coupling of expression of a therapeutic protein (HlyE; Ryan et al., 2009) and the Φ X174 gene E with a *Vibrio fischeri* quorum sensing circuit that resulted in oscillatory expression of the effector gene, individual cycles of protein expression followed by cell lysis occurred on a cyclical basis, and resulted in repeated rounds of protein expression and release that led to a therapeutic protein-dependent (HlyE) antitumor effect (Din et al., 2016). This systems have the potential to be used for expression control of other effector systems such as those outlined above.

Summary

Bacterial targeting of tumors offers a promising alternative to conventional cancer therapeutics. In mice, attenuated bacteria are safe, target tumors from a distant inoculation site, selectively replicate within tumors, and cause tumor suppression of tumor growth. These phenomena also occur in dogs treated with *Salmonella*, and in some cases resulted in complete regressions. However, based upon the studies with *Salmonella*, no significant antitumor effects have yet been shown in humans, even when the bacteria successfully targeted the tumors. Further exploring treatment of tumors other than melanoma remains of interest. Many approaches to conferring *Salmonella* with enhanced antitumor effects are being explored. Other on-going clinical studies, including those using *Clostridium* and *Listeria*, also have the potential to generate novel forms of cancer therapeutic bacteria.

Acknowledgments

I wish to thank John Pawelek, Brooks Low, Keith Joiner, Samuel I Miller, Martina Ittensohn, Sean Murray and David Quintero for helpful discussions. I disclose that I have financial interest in Avix Technologies and Magna Therapeutics. This work was supported by the National Institutes of Health (NIH) grant GM098207 to DB.

Introduction

An isolated phage particle on its own is fairly simple, consisting of one or more strands of nucleic acid (either DNA or RNA) enclosed in a protein capsid, often with additional structures in the form of a tail or, less often, a membrane. As such, it is a relatively inert, non-metabolizing, non-evolving complex of macromolecules. Place this encapsidated nucleic acid into its natural environment, however, and it veritably comes alive. Such a particle now can interact with a bacterial cell, harnessing cellular metabolism to replicate and produce offspring at the cell's expense; alternatively, the phage genome may contribute gene products to the benefit of both itself and its host. Offspring viruses, including spontaneous mutants, can compete intracellularly or infect new cells, potentiating rapid evolution of the virus population. Cells killed by viruses release dissolved organic carbon and other nutrients as well as DNA into the environment, in turn altering organism competition and other ecological interactions. Further driving changes to their communities, many phages in the process of transduction can actively transfer genes from one bacterial cell to another. Some bacterial sequences have even evolved to exploit transduction and transduction-like processes, resulting in the use of phage machinery to efficiently package and deliver plasmids and pathogenicity islands, as well as other phage-like elements. Phage ecology links phage molecular and structural biology to evolutionary biology. Indeed, phages have become model organisms in the study of all of these fields.

Whether comparing phage genotypes in the lab or observing entire populations of phages directly in nature, the study of phage ecology spans all levels of biological organization (Table 1). These levels range from individual phage particles to ecosystems comprised of phages, bacteria, other microbes, macroorganisms (animals, plants, fungi, and larger protists), and abiotic factors. In this article, we review how phages interact with their environments across these levels of organization, and we discuss how phages are detected and characterized in their natural environments.

Phage Population Ecology

The study of populations is central to understanding one of the major questions in ecology: what generates and maintains the diversity of the biological world? Populations are the major unit in which evolution occurs, so uncovering the forces that influence phage population ecology allows a detailed understanding of how and when phage evolution happens. Elucidation of population dynamics, and thereby of population ecology, requires consideration of the genotypes present in populations, how those genotypes confer individual differences in phenotypic fitness, and how individuals with similar or different genotypes interact. In this section, we review the major classes of phage-phage interaction, especially with respect to competition for their most important resource: bacterial cells.

Phage reproduction strategies

Decades of research have uncovered a diversity of molecular strategies which drive both phage ecology and evolution (see Bacteriophage (Overview)). For example, phage reproduction can involve the maturation and release – either by killing the cell or chronically infecting depending on the phage – of new virus particles into the extracellular environment. Alternatively, phage lysogenic strategies involve the replication of phage nucleic acid within infected bacterial cells but without immediate production of new virus particles. Though all phages can produce new virus particles, temperate phages are ones which also can display lysogenic strategies. Nevertheless, phages are sometimes misleadingly referred to as 'lytic or lysogenic' and thus presented as if these two strategies are either mutually exclusive from one another (though temperate phages by definition can display both) or are the only two strategies phages can employ (e.g., consider also chronic release).

Production of new virus particles is often described in terms of the lytic life cycle common to many phages, such as phage T2 (obligately productive) and phage λ ('strategically productive,' i.e., temperate). During the lytic cycle, a phage undergoes the following steps: (1) Adsorption to one or more cell-surface receptors; (2) Entry of the nucleic acid into the cell; (3) Cooption of cellular machinery; (4) Nucleic acid replication; (5) Assembly of phage particles; and (6) Cell lysis and release of new phage particles into the environment. The number of particles released per infected cell is the burst size, which can vary tremendously among different phages but often numbers hundreds per phage-infected bacterium (see Bacteriophage (Overview)). As noted, the final step of the lytic cycle (lysis) is not required for all phages, and indeed phages such as M13 (Table 2) are released without killing the cell

[☆]*Change History:* July 2018. AR Burmeister updated the text, including moving some content within Tables 1 and 2, regular text modifications, and figure caption modifications.

This article is an update of S.T. Abedon, S. Duffy, P.E. Turner, Bacteriophage Ecology, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 42–57.

Table 1 Levels of biological organization and example ecological interactions experienced by phages

Organization level	Definition	Ecological example
Individual	A single organism	
Population	All individuals of the same species within a specific location	Within a population, individuals compete for resources, such as phages competing to infect cells.
Community	All individuals of all species within a specific location	Within a community, one species exploits another, such as lytic phage infection and killing of bacterial cells.
Ecosystem	The community plus all abiotic factors in a specific location	Within an ecosystem, phage lysis of cells causes nutrient levels to increase.
Biosphere	The set of all ecosystems on Earth	Within the biosphere, abiotic nutrients and biotic entities flow between ecosystems.

Table 2 Phage types arranged by genomic characteristics

Nucleic acid	Strands	Super-coiling	Circularity	Genome sense	Segments	Morphology (%) ^a	Family (genus examples)	Genome size (kb)
DNA	Double	+	—	—	—	Contractile tail (14%)	Myoviridae (Mu, P2)	34–240
						Long, noncontractile tail (59%)	Siphoviridae (λ , T5)	22–121
						Short, noncontractile tail (24%)	Podoviridae (P22, T7)	16–70
	Single	—	+	—	—	Isometric, internal membrane (<1%)	Tectiviridae (PRD1)	15
						Isometric, internal membrane (<1%)	Corticoviridae (PM2)	9–10
						Spherical-pleiomorphic, enveloped (<1%)	Plasmaviridae (L2)	12
RNA	Single	+	+	+	—	Elongated (1%)	Inoviridae (M13)	4.5–8.5
						Isometric (1%)	Microviridae (ϕ X174)	4.5–5.5
	Double	+	—	—	+	Isometric, enveloped (<1%)	Cystoviridae (ϕ 6)	13
						Isometric (1%)	Leviviridae (MS2, Q β)	3.5–4.2
	Single	+	—	+	—			

^aApproximate relative abundances among electron micrograph-characterized cultured phage isolates.

(termed ‘chronic’ release instead of ‘lytic’). The primary ecological effect of productive infections is phage population growth, resulting in more phages in the environment.

Lysogenic infections often involve the integration of the phage genome directly into the bacterial genome (as done by phage λ) or instead replication of the phage genome as a plasmid-like element (as done by phage P1). In these forms, the hosting bacterium is referred to as a lysogen and the phage genome as a prophage, and phage replication is largely dependent on the bacterial host’s replication. Sometimes, a phage genome may simply lie quiescent in the bacterial cytoplasm, replicating neither productively nor lysogenically, in a state called pseudolysogeny.

Competition

Population ecologists often consider the mechanisms by which individuals of the same species interact to compete for resources. The outcome of these interactions is that some individuals will gain more resources than others, with the difference often expressed in terms of evolutionary fitness. For phages, fitness can be quantified directly in laboratory experiments by observing the relative changes in phage genotype frequencies over time. Alternatively, fitness may be approximated by measuring specific traits such as phage growth rates.

Ecologists generally consider two broad categories of competition within a population: scramble competition and contest competition. These categories differ in the way that individuals compete for and control resources. Scramble competition involves all individuals within a population competing for resources to which they all have equivalent access, while contest competition involves a small number of individuals controlling access to one or more resources. Individuals may experience combinations of scramble and contest competition at any given time as the two types of competition are not mutually exclusive.

An example of scramble competition commonly invoked by biologists is that of finches competing for seeds. One bird may more quickly pick up seeds with its beak and thereby outcompete the slower seed-picker, even though the two birds have equal access to seed resources. For phages, scramble competition will occur as different genotypes of the same species compete for bacterial cells. One phage may more quickly adsorb to cells and thereby outcompete slower-adsorbing phages, even though the two viruses otherwise have equal access to all of the cells.

With contest competition, one individual controls a resource and another individual can be harmed when attempting to access that resource. For example, a single male elephant seal can control a beach to ensure exclusive access to all mating events with

Fig. 1 Competition and outcomes of infection involving a single primary phage infection (Panel A), a primary phage infection of a cell with a resident prophage (Panel B), or both primary and secondary phage infections (Panel C). Successful infection and replication of phages depends on whether a cell is resistant to the phage, including via superinfection immunity or superinfection exclusion. When two phages initiate infections of the same cell at the same time, then mutual exclusion, partial exclusion, and the depressor effect can also alter the outcome of infection (Panel C). All barriers to replication depicted in Panels A, B, and C may occur within the same cell; individual barriers are shown here for simplicity and clarity.

females. To compete for mates, another male must fight the ‘beach master,’ a challenge that incurs risk of bodily harm or even death. For phages, contest competition occurs when one phage controls all of a cell’s resources, often by being ‘primary,’ i.e., the first to infect (Fig. 1).

Relationship between reproductive strategies and competition

Successful phage infection depends on several factors; foremost, a phage-susceptible cell must be sufficiently metabolically capable of supporting phage replication. The cell must also not contain other interfering phages that prevent the new phage from replicating (Fig. 1). A primary phage is the first phage particle to encounter a cell (Fig. 1(A)). This phage, if singly infecting, has been subject only to scramble competition: if its general rate of encountering, infecting, and replicating within cells is faster than other phage particles infecting other cells, then it will be more competitive and thereby have a greater fitness. See Bacteriophage (Overview) for other steps in the phage life cycle that influence phage replication rate and fitness.

The outcome of a phage infection is more complex when multiple phage particles or types are involved, potentially resulting in contest competition. There are two common mechanisms of phage contest competition. The first occurs during a process called ‘superinfection,’ when a phage infects a cell that already contains a prophage (Fig. 1(B)). Prophages can confer resistance to infection through superinfection immunity, preventing the incoming virus from replicating. The second mechanism, superinfection exclusion, occurs when a primary infecting phage interferes with the genome uptake of a subsequently adsorbing phage (Fig. 1(C)). These mechanisms, and others involving multiple adsorptions to individual bacteria, tend to be limited to related phages, such as those from the same population. In the case of less closely related phages, direct competition between phages coinfecting the same cell will tend to result in a favoring of one phage over the other by means other than superinfection immunity or superinfection exclusion.

Phage Community Ecology

Communities comprise all of the species that coexist within a given area, and for phage communities, this includes at least one phage population and one bacterial population. In nature, a community is unlikely to be as simple as a single phage species and a single bacterial species, but in the following section we will discuss how even such simple communities can be complex in their types of interactions.

Model communities with single populations of phage and bacteria

Communities consisting of only a single phage type and single host type have been extensively studied using laboratory microcosms and mathematical modeling. Many such communities display distinct predator-prey cycles as also observed with macroscopic organisms (Fig. 2) and have been useful for studying ecological and evolutionary principles in general, not just those specific to microbial communities.

Fig. 2 Model of population dynamics in a simple community comprised of a single type of lytic phage, a single type of susceptible bacterium, and resources for bacterial growth. This simulation shows so-called ‘predator-prey’ cycles caused by bacterial growth and death due to lytic phage infection. As phages (purple line) consume bacteria (green line) and produce more phages, there is an increase in phage abundance and a corresponding decrease in bacterial abundance. As bacterial abundance declines, phages have fewer cells for replication, so phage abundance declines. The decline in phage abundance allows more bacteria to grow, resulting again in greater phage growth, and ongoing propagation of these community dynamics. The bacterial resource (red line) is impacted indirectly by the phage population through the killing of the bacterial consumer.

Even simple communities comprised of a single phage species and a single bacterial species can have many types of ecological and evolutionary interactions, including:

- Harm to bacteria by lytically or chronically infecting phages.
- Benefit to bacteria through the contribution of temperate phage genes, a process termed lysogenic conversion.
- Evolution of resistance to phages by at least a portion of a bacterial population.
- Evolution of more productive phages including overcoming bacterial resistance mechanisms.

All of these effects involve interactions between a bacterial population and a phage population, and they exemplify the types of dynamics that can play out in ecological communities.

In nature, it is rare for communities to consist of only a single phage strain and a single bacterial strain, and even laboratory communities can quickly evolve increased diversity in terms of bacterial resistance to phages and phages overcoming that resistance (next subsection). Such experiments provide insight into how ecological interactions can generate and maintain diversity, a central question throughout all of ecology. For example, laboratory experiments and models show that phages can mediate coexistence of two bacterial genotypes if one genotype is phage sensitive and has a higher intrinsic growth rate. In the absence of phages, phage-resistant bacteria with lower intrinsic growth rates will tend to decline to extinction.

Bacterial resistance to phages and antagonistic coevolution

Four common categories of host-encoded resistance mechanisms exist, each with a different ecological impact:

- Envelope resistance: Phages fail to adsorb so retain their fitness; bacteria survive.
- Restriction-modification: Phages adsorb and are killed; bacteria survive.
- Abortive infection: Phages adsorb and are reduced in fitness; bacteria do not survive.
- CRISPR-Cas: Phages adsorb and are inactivated by bacteria which have gained genetic memory of the phage’s nucleic acid sequence.

The consequence of these mechanisms, as of phage-host incompatibilities more generally, is reduction in the number of susceptible bacteria that are available for phages to ecologically exploit.

If a cell carries a resistance mechanism, then a phage’s ability to replicate may be diminished; unable to switch to a new cell, an adsorbed phage particle thereby can suffer reduced fitness and often death. Thus, there can be substantial fitness benefit to phages in overcoming bacterial resistance mechanisms. The process by which bacteria evolve resistance mechanisms to phages and phages respond by evolutionarily overcoming those resistance mechanisms is termed antagonistic coevolution.

Phage interactions with more than just bacteria

Phages can parasitize bacteria, and these bacteria may be parasites of eukaryotic hosts, such as humans. Consequently, one question of increasing importance is how do phages impact human health? Research suggests that phages may naturally play a role in protection against bacterial pathogens of humans and other animals. On the other hand, many temperate phages carry genes encoding bacterial virulence determinants; in these cases, the resulting lysogenic conversion can potentially convert benign host bacteria into virulent pathogens. These virulence determinants include cholera toxin (*Vibrio cholerae*), Shiga toxin (*Shigella* and *Escherichia coli*), diphtheria toxin (*Corynebacterium diphtheriae*), and the botulism neurotoxin (*Clostridium botulinum*).

Phages also experience interactions with other phage species. Associated modes of contest competition occur when two phages successfully initiate infection of the same cell at the same time (Fig. 1(C)). These modes include mutual exclusion (one phage replicates and the other does not), partial exclusion (one phage replicates more than the other), or the depressor effect (both phages experience reduced replication).

Phage Ecosystem Ecology

In addition to interacting with other community members, phage populations can also shape (and be shaped by) their abiotic environment. Together the biotic and abiotic components of an environment comprise an ecosystem, with organism impact on ecosystems studied by ecosystem ecology.

Ecosystem effects of phage lytic and lysogenic lifecycles

In addition to the production of toxins, phages also alter environments by simply lysing bacteria. Cell lysis releases both phages and soluble nutrients, the latter which can be used as growth substrates by other bacteria. This process, termed the 'viral shunt,' changes the flow of energy and matter through ecosystems (Fig. 3). Without viruses present, the 'microbial loop' instead moves energy and nutrients from bacteria to their predators. For example, in aquatic ecosystems cyanobacteria serve as food for their protist predators. When phages are present, cyanobacteria serve as resources for both protists and phages. While protists incorporate biomass that can be assimilated up the food chain, phages incorporate only a small portion of the bacterial biomass, the rest of which is released back into the environment as dissolved organic matter/material (DOM) via the viral shunt.

Phage Environmental Microbiology

Phage environmental microbiology largely deals with the detection and characterization of phages in their natural environments. Three methodological categories of phage environmental microbiology include culture-based techniques, direct visualization, and sequence-based techniques. Together they reveal much of what is known of phage diversity.

Culture-based techniques

Culturing typically relies on growing phages in isolation with specific bacterial hosts, often first enriching phages found in mixed communities on target bacteria. The success of these methods depends, however, on the phage types being grown and the culturability of their hosts.

Fig. 3 Nutrient cycling and energy flow via the microbial loop and viral shunt in the ocean. Energy and matter flow through the microbial loop beginning with phototrophic carbon fixation by the cyanobacteria. The bacteria are consumed by protist grazers, which are consumed by zooplankton predators. Death and incomplete consumption release dissolved organic material into the ecosystem, providing nutrients for growth of cyanobacteria and heterotrophic bacteria. Phages increase turnover through ecosystems by breaking down bacterial biomass before it is assimilated at higher trophic levels.

Many phages of easily-cultured bacteria can often be readily grown in laboratory broth cultures. When added to bacterial cultures, the phages replicate and may lyse the bacteria sufficiently to allow detection of reduced cell densities by eye or using a spectrophotometer. The resulting product, called a 'lysate,' is then centrifuged to remove cell debris. Residual living cells can be removed with chloroform or a filter that allows the phage, but not the cells, to pass through. Once prepared, a purified phage stock can be characterized in terms of growth rate, adsorption time, lysis time, burst size, particle stability and other key fitness parameters. Such culture-based methods remain the standard for phage characterization, providing clear evidence that a substance is indeed a phage, and not something phage-like in terms of morphology, sequence identity, or effect on cells. Culture-based methods are also useful for characterizing basic ecological and evolutionary relationships among phages, including their host range, receptor use, optimal growth conditions, and fitness.

While culture based methods are useful for characterization of specific phages that can be grown in the lab, most phages are not readily propagated outside of their natural environments, in part because most host bacteria are themselves not easily cultured. Furthermore, culture-based methods reveal only a limited set of properties of phages, often one phage isolate at a time, so can be somewhat limited in their ability to characterize the diversity of the phage world. Therefore, culture-based methods are often used alongside direct visualization and sequence-based methods of phage detection.

Direct visualization

Direct visualization methods include microscopic imaging of purified or mixed phage communities. Transmission electron microscopy (TEM) is frequently used, as it allows resolution of particle morphology (Table 2) for mixed environmental samples as well as purified phages. Used on mixed communities, TEM can provide estimates of viral diversity and abundances in an ecosystem. Scanning electron microscopy (SEM) is also used but provides lower resolution, making phage particle morphology difficult to determine. Epifluorescent staining and microscopy is often more affordable than TEM and SEM, although it provides even lower resolution. On the other end of the spectrum, cryo electron microscopy (cryo-EM) can allow exquisite resolution of single phage particles, ideal for the detailed study of purified phages and their molecular interactions with bacterial host cells. One limitation of direct visualization methods is that they cannot distinguish between infectious virions and other virus-like particles, such as encapsidated bacterial genes called 'gene transfer agents,' defective viruses, and others.

Sequence-based techniques

Sequence-based methods can determine the content and diversity of phage genomes regardless of whether a phage can be grown in the laboratory. Therefore, these methods can be used independently of or in conjunction with culture-based and direct-visualization methods. Phage metagenomics – the mass sequencing of whole phage communities – is often instead called 'viral metagenomics' or 'viromics,' because preparation methods do not necessarily separate phages from the viruses of archaea and eukaryotes. Metagenomic approaches have been used to characterize phages from many environments, including aquatic systems, animal microbiomes, and terrestrial communities. Like bacterial metagenomics, phage metagenomics has been rapidly evolving from a tool of natural history to one that is used to test hypotheses, compare treatment groups, and make predictions.

For mixed communities from natural environments, many of the sequencing technologies and analysis tools used for bacterial communities are being adapted for virus communities. However, unlike bacteria that share conserved genes, such as the 16S *rRNA* genes frequently used in sequence-based diversity studies, phages have no universally shared sequences. Furthermore, phage genomes can differ according to various nucleic acid forms, included ssDNA, ssRNA, and dsRNA (Table 2), so methods that rely on, for example, only DNA sequencing may miss large portions of viral diversity. Other approaches first convert RNA genomes into DNA genomes for sequencing. Together, these methods can allow separate descriptions of the 'dsDNA virome,' the 'RNA virome,' and so on. Nevertheless, viral metagenomics is revealing an unprecedented amount of sequence diversity within virus and virus-like particles.

Conclusion

Phage ecology is a rapidly growing and changing field. Population-focused approaches study the mechanisms of ecological and evolutionary change and have made phages into model organisms not only for molecular biology, but also for ecology and evolutionary biology, with new phages discovered continuously. Meanwhile, sequence-based detection and population sequencing are revealing unprecedented snapshots of the diversity of the viral world, and these methods continue to grow more powerful and sophisticated. Combined, all of these approaches have transformed bacteriophage ecology into a highly dynamic field with many open questions and much room for discovery.

Glossary

Adsorption A series of events, culminating at a minimum in free phage attachment to a bacterium, involving virion movement (via diffusion), virion encounter with a bacterium, virion attachment, and, depending on authors, transfer of the phage genome into the bacterial cytoplasm.

Capsid The proteinaceous structure that contains the phage genome.

Chronic release Extrusion or budding of mature virions from infected bacteria without cell lysis; chronic release neither destroys the bacterium nor ends the phage infection.

Free phage A mature phage (virion) particle that is not found associated with a bacterium.

Induction (prophage induction) The transition of a lysogenic infection to a productive one, involving expression of numerous prophage genes that otherwise remain quiescent in an uninduced lysogen.

Lysis Release of mature virions from an infected bacterium via the destruction of the bacterium, ending the phage infection.

Lysogeny A phage infection in which phage virions are not produced and the phage genome replicates only so as to continue infecting bacterial progeny produced via binary fission. Typically this involves phage existence as a prophage which is integrated into the bacterial genome.

Lytic cycle A productive phage infection that ends with bacterial lysis and release of free phages.

Lytic phage A phage that displays a lytic cycle given productive infection; lytic phages appear to be the most common of phage types. An obligately lytic phage cannot display a lysogenic cycle.

Productive infection Phage infection that results in production of free phages.

Prophage The phage genome as it exists during lysogeny.

Temperate phage A phage that is capable of displaying lysogeny, though infections by temperate phages often are productive rather than leading to lysogeny.

Virion An infectious viral particle.

Introduction

Viruses are obligate intracellular parasites and may be categorized in terms of the types of cellular organisms that they infect. Three cell types exist, members of domains Eukarya, Archaea, and Bacteria. The viruses that infect the bacteria, for historical reasons, are called bacteriophages, or phages for short, meaning that they are “eaters” of bacteria. Since most environments—including our own bodies—contain numerous bacteria, phages are found almost everywhere. Phage biologists have found phages in most environments that can support bacterial growth, often in ratios of phage-to-bacteria of 10-to-1 or more. As there exist estimates of total bacterial numbers of approximately 10^{30} , there consequently is an expectation that there are 10^{31} or more total individual virus (mostly phage) particles, making phages Earth’s most numerous “organisms.” Bacteria are highly diverse with perhaps millions of species of these prokaryotes. Phage-bacterial interactions therefore are quantitatively vast (huge numbers of interactions) and qualitatively diverse (huge numbers of environment types, bacterial-host types, and also individual phage types). In this entry we provide an overview of this enormous diversity of phage types, variations on phage biology, and the importance of phages in the laboratory, in environments, and, potentially, in the clinical setting.

Primer on Phage Biology

F. W. Twort (in 1915) and Felix d’Hérelle (in 1917) both described phages as macroscopic phenomena: the dissolving of bacterial colonies, the clearing of turbid broth cultures of bacteria, and the formation of holes (plaques) in turbid “lawns” of bacteria. Confirmation of phages as viruses awaited the invention of the electron microscope in the early 1940s. Subsequently, phages were harnessed toward elucidating the basic molecular mechanisms of life, and are credited with extensive contribution to the formation of the scientific subdisciplines of molecular biology and molecular genetics. In this section we provide an overview of the phage life

[☆]*Change History:* April 2019, ST Abedon updated all the text and references.

cycle, which by definition must include at some point an extracellular, virion state. We then discuss major criteria by which phage biologists distinguish among different phage genes and different phage types.

Phage Life Cycle

We begin our description of the phage life cycle with the formation of a free phage, which initiates the phage extracellular search for new bacteria to infect. The extracellular search culminates with adsorption. Entrance of the phage genome into the cell begins the infection period, typically described as a latent period. The latent period ends either with phage-induced bacterial destruction (lysis) or via an extruding or budding of maturing phage virions across the bacterial cell envelope (chronic release, which occurs in a manner that does not lead to immediate bacterial death). Infections that result in phage release can be described as productive. Alternatively, phage infections can enter a latent state (lysogeny or pseudolysogeny) or can fail to successfully infect (phage restriction or abortive infection). See Table 1 for a summary of phage infection types and their characteristics.

Phage Genes

Functionally, we can differentiate the genes and factors involved in a phage infection into three types: products of bacterial genes, products of phage genes that are expressed and employed during phage infection, and phage genes whose products are associated with released phage virions. Though useful when viewing phages as evolving, ecological entities, nevertheless not all of the gene products employed by phages may be unambiguously differentiated into these three categories. For example, phage virions can carry some proteins that are then employed only once subsequent infection has occurred. Also ambiguously, many phage genes encode proteins that are involved in virion assembly but which nevertheless are not represented as part of the resulting virion.

Evolutionarily, we can distinguish phage genes in terms of their potential to coevolve with other phage genes. Coevolution among phage genes is often cited as an explanation for the genetic linkage—similar location on genomes—of genes encoding interacting phage capsid proteins, such that a mutation in one gene requires a corresponding mutation in another. Alternatively, phage genes can evolve to become further refined in their interactions with smaller molecules (e.g., nucleotides), generic versions of larger molecules (e.g., as with phage exonuclease action on bacterial DNA), or with specific bacterial macromolecules, for example, RNA polymerase or the phage receptor molecule found on the surface of host bacteria. The latter interactions also can be coevolutionary should antiphage adaptations by bacteria lead to the evolution of counter adaptations by phages (antagonistic coevolution).

Phylogenetically, we can distinguish phage genes in terms of where those genes came from. Many or most genes associated with phages, for example, likely have been evolving within phage genomes for millions or even billions of years. Other genes, or portions of genes, appear to be newly acquired from bacterial genomes. Some phage genes seem to readily move from phage genome to phage genome due to genetic recombination following coinfection of individual bacteria by different phage types. Still other genes, such as virion structural genes (below), appear to move between phage genomes as multigene complexes, presumably as a consequence of the difficulty in splitting apart these coevolved genes while still retaining function (above).

Metabolically, phage genes broadly may be sorted into at least six classes: (i) phage genes involved in the metabolic takeover of host metabolism (e.g., gene products that shut down the transcription of bacterial genes), (ii) phage genes involved in establishing or maintaining a latent state (e.g., lysogeny), (iii) phage genes involved in preparing the infected cell for phage-progeny maturation (e.g., genes involved in prophage induction, nucleic acid repair, and nucleic acid replication), (iv) genes that express phage-virion

Table 1 Different types of phage infections

Type of infection	Does the phage genome replicate?	Are free phages produced?	Do bacteria survive?	Do phages survive?	Comments
Lytic	Yes	Yes	No	Yes	These are productive cycles that release free phages via phage-induced bacterial lysis, which destroys both bacterium and phage infection
Chronic	Yes	Yes	Yes	Yes	These are productive cycles that result in the formation of free phages without destroying either the infected bacterium or the phage infection, a.k.a., persistent infections
Lysogenic	Yes	No	Yes	Yes	With lysogenic cycles, phage genome replication occurs without production of virion progeny; replicated genomes segregate into daughter bacteria
Pseudo-lysogenic	No	No	Yes	Yes	By one definition these are infecting phage genomes that do not replicate and do not produce phage progeny, a quiescent state that can lead to productive or lysogenic cycles
Restricted	No	No	Yes	No	Passive or active bacteria-mediated inactivation of infecting phages such as via restriction endonucleases; a broader definition does not specify whether bacterial hosts survive
Abortive	No	No	No	No	Abortive infections involve the inactivation of both infected bacterium and infecting phage; a broader definition replaces infecting phage inactivation with infecting phage inability to produce plaques

Based on table presented by Abedon, S. T. (2008). Phages, ecology, evolution. In: S.T. Abedon (ed.), *Bacteriophage ecology*. Cambridge, UK: Cambridge University Press.

structural and virion-assembly proteins, (v) gene products that process and package newly replicated phage genomes into virions, and (vi) gene products required for release of assembled virions from the host cell either by lysing the host cell or by exporting the newly assembled virions through the cell envelope. Though it is traditional to view phage genes as distinct from bacterial genes, in considering these genes as models for the basic metabolic workings of life there is no fundamental difference between a phage gene versus bacterial genes encoding parts of complex molecular machines such as those involved in gene transcription.

Genetically, phage genes required for productive infections can be described as encoding essential functions. Mutations in these genes tend to be lethal or instead effectively so by substantially decreasing the number of progeny produced during infection such that phage plaques do not form. Phages also encode nonessential genes. Inactivation of these genes still allows production of viable progeny. The yield of progeny phages per infection often can be reduced, but not to the point that phage propagation is severely curtailed. Alternatively, if infection yield is not reduced, and additional phage growth parameters are not otherwise affected, then it may be that these nonessential genes encode proteins that are only needed for infection of certain hosts or under certain metabolic or environmental conditions. The number of nonessential genes found within a phage genome can be significant. Sixteen of the 50 genes of bacteriophage T7 (32%) are nonessential, for example. Lastly, it should be noted that some bacteriophage genomes contain other genetic elements such as introns or can encode inteins (self-excising protein segments).

Phage Gene Expression

The expression of phage genes typically occurs in a well-defined temporal order, one which typically “makes sense” in terms of the metabolic functions of these genes. In addition, as bacterial parasites, phages rely on the host cell for a range of metabolic functions. In the most genomically complex phages, functions supplied by the host cell may be limited to cell structural elements (membranes, cell wall), energy transduction machinery (e.g., cellular respiration), and protein synthesis apparatus (ribosomes). Large, more complex, and usually obligately lytic phages often shut down host gene expression soon after initiating an infection and may degrade the host genome. Simpler phages usually rely more on the host cell for metabolic functions. Lysogenically infecting as well as chronically released phages are reliant on host cell functions over longer periods and presumably as a consequence are less disruptive of these functions.

Upon infecting a host cell, phages begin expressing what are termed early or immediate-early genes. The promoters of these early genes—DNA sequences where RNA polymerase binds to initiate transcription—tend to more closely resemble bacterial promoters than those of later-expressing phage genes. The early genes of obligately lytic phages produce proteins involved in coopting bacterial gene expression. These include RNA polymerases and sigma factors (which modify RNA polymerase promoter recognition). Phage-encoded sigma factors favor transcription of viral genes over bacterial genes. Expression of these early genes is followed by delayed-early or middle genes (or, in some cases, late genes) that initiate phage genome replication and related functions. Phages that encode their own DNA or RNA polymerase will begin synthesizing that enzyme along with proteins involved in nucleic acid metabolism. Collectively, early and middle genes are sometimes referred to as prereplicative genes, that is, genes expressed prior to the initiation of phage genome replication.

The first proteins made by temperate phages are those that determine whether lysogeny or instead a lytic infection will immediately occur. Expression of these early genes is sensitive to the metabolic state of the bacteria or to signals from communication peptides produced by previously infecting phage that allow an estimate of the number of previous infections in a location. The resulting relative differences in levels of expression of key phage proteins commits the phage to either the lysogenic or lytic pathway by activating one set of regulatory genes and inhibiting a second set of regulatory genes. If the phage is to enter the lysogenic phase, then proteins are produced that bring about, for example, the integration of the phage genome into the host genome, or which instead stabilize the phage genome in an episomal (plasmid) form. Proteins are also produced that prevent (by inhibition or termination) expression from the remainder of the phage’s genes. If the phage enters the lytic cycle, then it begins expressing early and middle lytic genes and blocks expression of genes required for lysogeny.

During the postreplicative phase of the lytic cycle, both obligately lytic phages as well as induced temperate phages begin expressing late genes, including structural genes that will make up the phage virion, processing proteins (if they encode any) that can be required to mature the virion, and packaging proteins which place newly replicated phage genomes into the phage particle. Late genes are much more dependent than earlier genes on phage-encoded functions for expression. In some phages, such as phages T3 and T7, late-gene expression is dependent on a phage-encoded RNA polymerase. In other phages, such as phage T4, the switch to late-gene expression is brought about by modification of the *Escherichia coli* RNA polymerase complex by phage proteins. In bacteriophage λ and related phages, expression of late genes begins by a combination of derepression (loss of a repressor protein allowing RNA polymerase access to promoters) and antitermination (caused by a phage protein that allows transcription to pass through transcription termination sites).

A few phages also encode unusual late genes that neither contribute to the phage virion nor to phage release. Notable examples of this are lambdoid phage strains, which both lysogenize pathogenic *E. coli* strains such as the O157:H7 serotypes and encode a type 2 Shiga toxin. In these phages, the toxin genes are located next to the genes inducing cell lysis and are expressed with those genes late in infections. The release of the Shiga toxin from the cell is also dependent on phage-induced cell lysis. There is debate as to whether these toxin genes ought to be considered phage genes or, instead, as a form of phage-located bacterial genes. As discussed further below, numerous additional phage-encoded genes that express bacterial virulence factors are known including genes producing cholera toxin (as associated with the bacterium *Vibrio cholerae* and the disease cholera), diphtheria toxin (produced by *Corynebacterium diphtheriae* and giving rise to the disease, diphtheria), and numerous additional virulence factors displayed by bacterial pathogens such as *Clostridium* spp., *Pseudomonas aeruginosa*, *Salmonella enterica*, *Staphylococcus aureus*, and *Streptococcus pyogenes*.

Phage Diversity

Phages, like viruses in general, are typically differentiated in terms of their infection type, virion morphology, or genome characteristics. Based on infection types, a phage may be described as a lytic versus chronic releaser or as obligately lytic (a.k.a., virulent) versus temperate. Based on virion morphology, phages may be described as tailed (also known as binary), cubic (including icosahedral), helical, or pleomorphic. Tails can be long or short, flexible or rigid, and contractile or noncontractile. Phage genomes can be single-stranded (ss) DNA, double-stranded (ds) DNA, ssRNA, or dsRNA. Genomes can also be segmented (multipartite) or nonsegmented (monopartite). The majority of phage isolates are tailed and so far as is known all tailed phages display dsDNA, monopartite genomes as well as lytic cycles (though many are also temperate). See Table 2 for a description of the various phage families and Fig. 1 for the basic morphologies of each phage family.

Increasingly, phages are differentiated in terms of their genome nucleotide sequences, and whole genome sequencing provides a wealth of information useful for inferring phage genomic functionality and evolutionary history. The analysis of phages in this manner is referred to, generally, as the study of phage genomics. This type of analysis is especially important in classifying phages at the genus and subfamily levels and has led to the distinguishing of many new genera. The 2008 release of virus taxonomy by the International Committee on Taxonomy of Viruses (ICTV) described a total of 18 genera in the Caudovirales (tailed phages) order. In the 2011 release, there were 37 genera with most of the increase in the Myoviridae and Podoviridae families. As of the 2013 release, there are 39 genera.

Table 2 General characteristics of major phage types infecting eubacteria

Family	Genome	Morphology	Release	Examples
Cystoviridae	dsRNA, segmented	Enveloped	Lytic	φ6
Inoviridae	ssDNA, circular	Helical, rod shaped or filamentous	Chronic	f1, fd, M13, CTXΦ
Leviviridae	ssRNA, linear	Icosahedral	Lytic	MS2, F2, Qβ
Microviridae	ssDNA, circular	Icosahedral	Lytic	φX174
Myoviridae	dsDNA, linear	Tailed, contractile	Lytic	Mu, P1, P2, T2, T4, T6, RB69
Siphoviridae	dsDNA, linear	Tailed, noncontractile, long, flexible or rigid	Lytic	λ, N15, SPP1, T1, T5
Podoviridae	dsDNA, linear	Tailed, noncontractile, short	Lytic	Gh-1, N4, φ29, φA1122, φYe03–12, P22, SP6, T3, T7

Fig. 1 Basic morphologies of different families of virions of prokaryotes. Green represents nucleic-acid encasing capsid protein. This includes the heads of tailed phages. Blue indicates tails and other adsorption organelles (tail fibers and other appendages on tailed phages, however, are not shown). Pink is lipid of various kinds. The contractile portion of the Myoviridae tail is indicated with diagonal lines. The flexibility often seen with the Siphoviridae tail is not indicated. All shown heads are isometric but in addition tailed phages often display elongated “prolate” heads. The Inoviridae are depicted as two types: short rigid rods (genus Inovirus) and long flexible rods (genus Plectovirus). Long rigid rods of genus Plectovirus also exist. Plasmaviridae are unusual budding viruses of mycoplasma bacteria, which lack cell walls. Only a subset of known archaeal virus morphologies are depicted. Adapted from that of Ackermann, H. W. (2006). Bacteriophage classification. In: R. Calendar and S. T. Abedon (eds.), *The bacteriophages* (2nd edn). Oxford: Oxford University Press, pp. 8–16.

Phages additionally may be distinguished in terms of their host range, that is, what bacterial types they are capable of infecting. In general, however, host-range based classification is less useful toward obtaining a facile understanding of common themes of phage biology. Perhaps the best illustration of the difficulty of host range-based classification are phages P1 and Mu which are each able to switch between different host ranges by utilizing alternate phage-encoded adsorption proteins. In addition, it is increasingly common to characterize phages through nucleic acid sequencing without prior phage culturing. This can be accomplished via the techniques of metagenomics whereby a sampling, often rather large, of environmental DNA (or RNA) is sequenced, resulting in what are described as viromes. In addition, even whole phage genomes can be sequenced via these related techniques, again without prior culturing. As a result of these approaches, huge amounts of phage genetic and genomic information is being generated, often with little appreciation of phage host range.

Importance of Phages

Bacteriophages play important roles—some positive, some negative, some current, some historical—in biology, in ecology, and in health. In this section we provide an overview of these roles. These include, in order of presentation: Phage use as molecular model systems; phage and phage product use as molecular tools (including phage-display technologies); phage use in bacterial identification; the problem of phages as contaminants; the promise of phage therapy (i.e., phages as antibacterial agents); use of phage-derived molecules as antibacterial agents or in antibacterial drug discovery; use of phages as gene or toxin delivery vehicles (such as for fighting cancer or as gene-therapy vectors); phage use as indicators and tracers; the study of phage interaction with animal bodies; the study of phage ecology; phage-mediated transfer of genetic material between bacteria (i.e., transduction); the role of phages in bacterial pathogenesis; and the use of phage models in the general study of organismal ecology and evolutionary biology.

Phages as Molecular Model Organisms

Phages have been used as model organisms for almost as long as their biological nature was recognized (e.g., the use of phages as model viruses by Emory Ellis in the late 1930s). In part this was and is due to their ease of culturing but also due to their amenability to chemical as well as biological manipulation. Bacteriophages were used in key experiments in the history of molecular biology including understanding the structure and composition of the gene, mutagenesis, and gene regulation. Two notable examples are a demonstration that DNA is the genetic material in phage T2, by Hershey and Chase, which served as the second and universally convincing system for which DNA was demonstrated to be the hereditary material, and the existence of mutations within a population before selection, by Luria and Delbrück, which ushered in the now obvious understanding that bacteria, like peas and fruit flies, also possess experimentally accessible genetics.

Phages were used in many other key discoveries in the history of molecular biology. A partial list includes: recombination of phage chromosomes; viral encoding of metabolic enzymes; restriction/modification enzymes; fine structure of the gene; mechanisms of mutation; existence and function of mRNA; nature of the genetic code; colinearity of genes and proteins; conditional lethal mutations, nonsense and frameshift mutations; protein assembly pathways; role of sigma factors in transcription; in vitro gene expression; noneukaryotic introns; and the identification of DNA replication fork proteins.

Phages as Molecular Tools

Just as bacteriophages played a critical role in the development of molecular biology, bacteriophages have been vital in genetic engineering technologies. The use of phages as cloning vectors (carriers of cloned genes), for example, takes advantage of the ability of phages to infect a large population of bacteria essentially simultaneously and begin expressing the cloned gene in a temporally coordinated fashion. This has allowed the expression of proteins that would otherwise be lethal to bacteria. Likewise, the ability of some phages to integrate their DNA into specific sites in the bacterial genome allows for bacterial strain modification that would prove difficult by general recombination.

Many different phages have been used to develop genetic engineering tools and techniques, but three have played especially important roles. These are the temperate phage λ (and related lambdoid phages), the chronically released filamentous phage M13 (and its cousins f1 and fd), and the obligately lytic phage T7. Phage λ along with the various filamentous phages have been used to develop a series of gene expression and cloning vectors. The organization of the λ genome is especially useful as a cloning vector since the central one-third of the 48,000 base-pair genome can be deleted, leaving ample room for inserted genes. This segment includes all of the genes responsible for lysogeny, committing the derived phage to a solely lytic life cycle. Phages M13 and T7 have been widely used in phage display technology (below). Functional elements of other phages, including the promoters of phages T3, T7 and SP6 as well as the phage f1 origin of replication, have come to be used in a wide variety of cloning vectors. Filamentous phages (M13, f1) lack a large dispensable region but have other uses since cloning vectors derived from these phages can form a plasmid-like intermediate in the infected cell and replicate and package their genomes in a ssDNA form. Single-stranded DNA is particularly useful for a number of genetic engineering procedures including oligonucleotide-directed site-specific mutagenesis, synthesis of strand-specific probes, subtractive hybridization, and DNA sequencing. Likewise, there are more specialized functional elements, such as the *cin* recombinase (also called *cre* recombinase) and recognition sites (*cix-cin* sites) of bacteriophage P1, which

have been adapted to make a powerful site-specific recombination system: the Cre/Lox system. As well, particular phage enzymes have proven useful in a variety of molecular biology techniques. These include DNA polymerases, RNA polymerases, DNA ligase, single-strand binding protein and others. Bacterial adaptations to resist phage infection have also provided important molecular tools. Restriction enzymes are classic examples but more recently the CRISPR-Cas system, a prokaryotic system for gene silencing of incoming bacteriophage genes, has been adapted for use in eukaryotic cells and organisms. Several temperate bacteriophage homologous recombination systems have been repurposed into systems for assembly of genetic constructs, a technique described as recombineering.

The development of some of these enzymes and other systems has been aided by advances in genome sequencing as well as metagenomic analysis of environmental samples. These both allow the rapid and inexpensive identification of useful novel versions of genes from new species of bacteriophages.

Phage Display

A powerful phage-based genetic engineering tool is phage display. Phage display is a form of high throughput screening that allows large numbers of peptide segments to be screened for binding to a target. For these systems, a library encoding short peptide segments is inserted into a gene encoding a phage-virion capsid protein. Insertion of these peptides is accomplished at a location that leaves the added peptides on the surface of the virion particle, in a manner that minimally disrupts virion functionality, and where they are able to interact with other proteins or materials. Depending on the virus vector used, the displayed peptides may be in head proteins, receptor proteins, coat proteins, etc. The resulting recombinant phages are exposed to a target protein, or other material, that is usually fixed to a surface or other solid matrix. If the inserted protein segment has affinity for the target then the phage will bind to it. Noninteracting phages are washed away and the bound phages are recovered. The recovered phages are then grown to produce a population enriched for phages whose inserted peptide binds the target. These steps, which are sometimes termed “biopanning,” are repeated through several (commonly three to five) rounds to obtain phages containing the tightest binding segments under the conditions used.

Phage display has been used in finding peptides that bind to a wide variety of targets and which are useful for many purposes including the generation of antibody and other protein-binding peptides (which are useful for epitope mapping and for vaccine development); virus-receptor binding peptides (which are useful in drug discovery); novel DNA binding peptides, especially ones that show sequence specificity (which may be employed in designing novel gene regulatory proteins); and peptides that bind to inorganic materials (such as semiconductor materials which are being used to create hybrid organic-inorganic materials). Dozens of monoclonal antibody-based drugs that utilize binding-site peptides have been derived using phage display. Not all phage display systems work equally well for a given application and finding the most appropriate system for a particular target is sometimes a matter of trial and error.

Phage Use in Bacterial Identification

The treatment of bacterial disease, or otherwise dealing with bacterial contamination (including by quarantining), is eased via rapid and accurate bacterial identification. For decades phages have played important roles in such identification. Early techniques involved phage typing, which is bacterial identification (and classification) on the basis of phage susceptibility. Toward bacterial detection, phages may be added to bacteria-containing cultures, looking for phage amplification that occurs only if phage-susceptible bacteria are present. Alternatively, phages endogenous to a culture (that is, naturally occurring) and that infect specific bacteria types, may be used to infer bacterial presence. More recently, phages have been tagged with reporter molecules, such as fluorescent markers, or have been bioengineered to express reporter genes, which provide light or instead color changes within a culture only if phage infection successfully occurs. The latter approach is especially useful in identifying bacterial antibiotic susceptibility—as well as antibiotic resistance—since antibiotics capable of blocking phage infection (due to blocks on bacterial metabolism) can also block reporter-gene expression. All of the techniques are dependent in their efficacy on the relatively narrow host range displayed by many phages, that is, the potential by phages to infect only a limited number of bacterial types. Several phage-based systems are now or have been available commercially including systems for detection of *Bacillus anthracis*, *Yersinia pestis*, *S. aureus* and *Mycobacterium tuberculosis*. Phage based detection of *M. tuberculosis* is especially advantageous in providing results in a day compared to several weeks of traditional culture-based identification.

Phages as Contaminants

Biotechnology employs organisms to produce useful products and in the modern world this typically involves employing some form of recombinant DNA. As the use of microorganisms in biotechnology has become more sophisticated, especially beyond their use, for example, as naturally acquired cultures during food production, the tendency has been to employ pure cultures. A pure bacterial culture, however, is especially susceptible to inactivation by contaminating phage. That is, a single bacterial type may be wiped out by a single phage type, whereas wild microbial communities, consisting of multiple bacterial types, are more likely to contain bacterial populations which are inherently resistant to any given phage type. With the advent of modern culturing techniques, along with bacterial culturing on industrial scales, phage contamination thus can and often does lead to catastrophic fermentation failure.

Fermentation failures are especially prevalent in the production of fermented dairy products, such as cheeses, since the milk is not sterilized prior to use and therefore can contain phages specific to the starter-culture bacteria employed to create the specific characteristics of the fermented food. A variety of steps may be taken to minimize phage contamination, or its impact. These include modifications to fermentation facilities or to the bacterial strains employed. In addition, the CRISPR-Cas systems mentioned above were first recognized as antiphage mechanisms in conjunction the characterization of phage resistance in bacteria employed in dairy fermentation.

Indigenous phages have been implicated also in the failure of natural bacterial assemblies. These may include the lactobacilli, vaginal normal flora that otherwise can serve as a bulwark against bacterial vaginosis. It has been hypothesized that cigarette smoking can lead to bacterial vaginosis as a consequence of prophage induction in vaginal lactobacilli lysogens. Though long studied, the role of endogenous, naturally occurring phages in limiting growth of normal microbiota bacteria as well as pathogenic bacteria is only minimally understood or even appreciated.

Phage Therapy

While phages can be a nuisance due to their ability to infect and thereby inhibit or destroy bacterial cultures of industrial importance, that same propensity can be harnessed to reduce numbers of instead nuisance bacteria, including bacterial pathogens. This phage application as anti-bacterial agents is described as phage therapy. The history of phage therapy is almost as long as the history of phage study itself. In parts of Eastern Europe and the former Soviet Union, phage therapy has been used more or less continuously since the 1930s. But phage use as antibacterial therapeutic agents was largely discarded by Western medicine as a consequence of inconsistent results and especially after the widespread adoption of antibiotics. Phage therapy has a number of advantages over traditional antibiotics, however. Phages are self replicating, minimally toxic, and easily isolated. Furthermore, phages display a “narrow spectrum of activity” (which for phages we would describe also as their host range), meaning that only relatively few bacteria are susceptible to a given phage strain. As a consequence, unlike antibiotics with their often broader spectrum of activity, phage therapy has much less potential to cause the “collateral damage” (a.k.a., dysbiosis) of destroying beneficial bacteria along with pathogenic, target bacteria. Phage therapy therefore is less likely to give rise to side effects such as overgrowth of opportunistic pathogens, so-called superinfections, that sometimes occur such as with antibiotic-associated vaginal yeast infections or *Clostridium difficile*-associated colitis.

There are some practical limitations to phage therapy. The specificity of phage infections means that there is no equivalent to a broad-spectrum antibiotic. Identification of an infection’s causative pathogen is necessary although to some extent this can be by-passed by using cocktails consisting of multiple phages possessing diverse host ranges. Also, just as bacteria can become resistant to antibiotics, they can become resistant to bacteriophages. Unlike antibiotics, however, this resistance is not difficult to overcome, either through bacteriophage mutation or substitution of another species of bacteriophage that attacks the same pathogenic host. Finally, there are some bacterial infections that are not amenable to phage therapy due to bacterial dissemination to body sites that are not be easily reached by phages, including the targeting of intracellularly infecting bacterial pathogens such as various *Mycobacterium* species. Alternatively, phages can be effective against certain bacterial infections in which antibiotics are less potent, such as against biofilm-associated bacteria.

The other limitation to use of phage therapy is regulatory. The biological nature of bacteriophages is not well suited to a regulatory pathway built to test drugs that do not have the capacity to evolve during treatment or that will need periodic reformulation to counter pathogen resistance. But the growing problem of antibiotic resistant bacteria has created renewed interest in phage therapy. Clinical trials for treatment of bacterial infections with phage are underway.

An alternative approach is the development of phages as decontaminating agents. Phage-based products are available from several companies for treating food products contaminated with *Listeria monocytogenes*, *E. coli* O157:H7 and *Salmonella*. Phage mixtures formulated for treating bacterial infections of plants are also being marketed.

Phage-Derived Enzybiotics

Another promising therapeutic use is not of whole phages but rather certain purified phage-encoded proteins that possess antibacterial properties. Most notably are phage endolysins, or simply “lysins,” which are responsible for breaking down the bacterial cell wall to terminate lytic infections. They can be applied exogenously to various bacteria, especially Gram-positive organisms, to lyse and thereby kill those bacteria. This killing is similar to that effected by the animal enzyme lysozyme but with higher specificity and effectiveness.

A second category of phage enzymes that possess antibacterial properties are known as extracellular polymeric substance depolymerases, or EPS depolymerases for short. These are capable of dissolving the “glue” that binds bacterial biofilms (i.e., EPS). Like lysins, EPS depolymerases can display high specificities, in many instances so high that these enzymes can be limited in their activity to only one or a handful of strains within a bacterial species. During phage infections there also are often phage proteins that are more subtly lethal to their bacterial hosts via interactions with especially internal bacterial components. One technology that is being explored is to use these proteins, and where they bind to host molecules, as guides toward the discovery of molecules that could serve as anti-bacterial drugs which do not require the phage virion to gain access to the bacterial cytoplasm.

Phages as Delivery Vehicles

Just as phage virions can be used to deliver DNA and thereby genes into host bacteria, so too phages can be engineered to deliver DNA as well as other molecules to nonhost bacteria or nonbacterial targets. In this way phages can be used as much more broadly acting therapeutic or instead prophylactic agents. Phages thus can be engineered to deliver lethal genes to eukaryotic cells, and do so with high specificity, such as to combat cancers. Alternatively, various toxins or instead antibiotics can be linked directly to the phage virions which, again with high specificity, can deliver these agents to target cells, such as tumor or cancer cells, or instead to bacteria that otherwise cannot support infections by these same phages. The utility of these latter processes is that cytotoxic drugs can be concentrated at their sites of action, just as phage therapy as more strictly defined represents a concentration of cytopathic effects to the immediate vicinity of their target bacteria, indeed to within the cytoplasm of those bacteria.

Phages also can package nontoxic materials, such as genes for gene therapy. In this case the phages are engineered so that they display both high specificity for target animal cells and carry DNA that is capable of being incorporated into and then expressed by those same cells, here as potentially located within our own bodies. Equivalent phages also can be employed to deliver genes that can be used to give rise to what is known as a DNA vaccine, that is, genes that are expressed within body cells that are able to elicit an immune response against their products, thereby stimulating a prophylactic immune response. As with many phage-based therapeutic technologies, key to phage-based gene therapy or vaccination is the genetic malleability of phages, which allows precise engineering of payloads as well as binding specificities.

Phages as Fecal Indicators and Environmental Tracers

Phages are found associated with fecal material because bacteria are abundant in the animal colon. As feces carry enteric pathogens capable of causing disease in otherwise healthy individuals, public health measures are directed toward both avoiding contaminating water supplies with feces and also monitoring water supplies for fecal contamination. In addition to certain bacterial types, phages can be employed as indicators in such monitoring, especially since, as viruses, they can mimic to a certain degree the survival characteristics of pathogenic enteric viruses. Also as mimics of enteric viruses, phages can be employed to test the potential of various water treatments for removal of such viruses, as well as virus removal, or containment, in a variety of nonwater contexts. Phages also are employed as relatively inert tracers of water movement, including of underground water supplies.

Phage-Based Interactions With Animal Bodies

Phages can be employed as a means of characterizing animal bodies, whether in terms of immune response, their removal from serum by nonspecific immunity, or in mapping tissues using phage display. Phage ϕ X174, especially, has been used to study the human humoral immune response, serving as a neoantigen (one not previously experienced by an animal) such that primary, secondary, and tertiary immune responses may be induced simply with subsequent vaccination. Antibody fragments produced by phage-display methods can also be used to target specific tissues. A phage-display library of antibody fragments is injected into an animal or, in certain instances, into humans. Recovery of phage virions from tissues and subsequent phage growth results in amplification of antibody fragments with specific binding properties and/or a mapping of antibody binding to specific tissues. This can be thought of as an *in vivo* biopanning. Phages that display tissue-targeting peptides may be employed in the course of gene therapy, serving as vectors targeting specific tissues. Here, phage DNA is replaced by appropriate gene-therapy vector DNA along with the therapeutic gene of interest. Phages may also serve as platforms for the display of antigens as vaccines. Because phage proteins also provoke an immune response, the phage itself may act as an adjuvant for the displayed peptide, that is, a substance that enhances protective immune responses.

Phage Ecology

Phage ecology is the study of the interaction of phages with their environments. Environments consist of biotic components (other organisms) or abiotic components (spatial, chemical, and physical factors). Subdisciplines of phage ecology consist of organismal, population, community, and ecosystem ecologies. Organismal phage ecology considers those phage adaptations responsible for phage survival or acquisition of new bacteria to infect. Phage population ecology considers groups of similar phages (loosely: a phage species) that are located within the same environment. Of concern are demographic factors, especially births and deaths, and how these factors are affected by phage and bacterial population densities. Communities consist of more than one species found within the same environment, and phage community ecology considers especially the interaction between phages and bacteria but also among phages or between phages and other organisms that are affected by phage-associated bacterial genes such as toxin genes.

Ecosystems consist of both biotic and abiotic factors contained within a reasonably well-delineated environment, such as a pond or a field, and phage ecosystem ecology considers especially the impact of phages on the movement of energy and nutrients through and within ecosystems. The interruption of such movement by viruses is especially important in aquatic environments, which are principally based on primary production (photosynthesis) that is performed by microorganisms such as cyanobacteria

(susceptible to cyanophages). In addition, the lysis of these microorganisms provides nutrients to heterotrophic bacteria, which serve as a second trophic base of aquatic ecosystems. Phage disruption of aquatic environments is thought to have a significant impact on the global carbon budget and therefore on the global warming that results from atmospheric carbon dioxide accumulation.

In addition, under the auspices of phage ecology is phage environmental microbiology, for example, the study of what phages are located where. A large component of such phage environmental microbiology is based upon metagenomic analysis, generating phage viromes. These viromes can then be compared between environments and phage physiological characteristics can be inferred by comparing virome-defining sequenced genes with those of other phages (and other organisms) that have been previously characterized and whose sequences have been deposited in databases. Increasingly a goal of these efforts is both full-genome sequencing and matching uncultured phages with probable environmental hosts.

Horizontal Gene Transfer

Transduction is the movement of DNA from one bacterium to another via a phage-virion carrier that has picked up bacterial DNA during infection. When the virion carrying the bacterial DNA infects another bacterium, the transduced DNA enters the recipient cell following the same entry path normally used by phage DNA. The DNA can then be incorporated into the bacterial genome via recombination. Transduction appears to play important roles in bacterial gene exchange, contributing in some cases substantially to bacterial adaptation.

In generalized transduction the DNA within a phage virion comes entirely from the bacterial genome. Generalized transduction can move bacterial genes without distinguishing among them, but is mediated by what are, as a consequence of the transducing DNA, nonviable phage virions. Specialized transduction occurs when a prophage excises from a bacterial genome in a manner that incorporates adjacent genetic material. Specialized transducers can retain phage viability, though likelihood of viability is reduced as the size of the bacterial genetic material transferred is increased. Phages also can incorporate bacterial genetic material via illegitimate recombination, forming what are known as morons (for “more” DNA). The Moron-Accretion Hypothesis posits that phage evolution occurs via the gradual incorporation of morons. Through coevolution with the rest of the phage genome, these morons either are eliminated or come to take on important phage functions.

Phage Role in Bacterial Pathogenesis

As transducers of DNA, phages play important roles in bacterial pathogenesis, the potential for bacteria to cause specific diseases. Upon reduction to lysogeny, many prophages can express genes that impact bacterial phenotype, including the production of exotoxins, which are eukaryote-affecting toxic proteins released from the bacterial cell. The expression of these genes is typically described as phage conversion or lysogenic conversion. In addition, following induction of a prophage, genes may be expressed that impact the characteristics of the harboring bacterial culture. Also, via generalized transduction, phages can transfer bacterial DNA as so-called pathogenicity islands, which are contiguous strings of genes that encode factors that contribute to bacterial pathogenicity.

While not all examples of lysogenic conversion contribute to bacterial pathogenesis (superinfection immunity by temperate phage does not, for example), there are many instances where bacterial toxins are encoded by temperate phages either in the lysogenic phase or, less commonly, during the lytic cycle. *Corynebacterium diphtheriae*, for example, is converted from a nonpathogenic form to a pathogenic form after specific phage infection. Likewise, about 5% of the genomes of pathogenic strains of *Salmonella typhimurium* are composed of prophage genomes, and these prophages contain some of the bacterial arsenal of exotoxin and other virulence factor genes. Pathogenic strains of *Vibrio cholerae* also owe much of their pathogenicity to phage conversion, with cholera toxin encoded by the temperate and filamentous phage CTXΦ. Another variation on this theme is seen in the production of Shiga toxin by pathogenic strains of *E. coli* such as the serotype O157. There are several related Shiga toxins but a typical feature is that their genes are located in prophage genomes and the harboring bacteria lack a mechanism to export the toxin. Instead, Shiga toxin is released when the prophage is induced and lyses the bacterium to release phage progeny.

Phages as Evolutionary and Ecological Model Organisms

In addition to the study of the ecology and evolutionary biology of phages, researchers employ phages to test more general ecological and evolutionary biological theories. In other words, just as phages have played extremely useful purposes as models for universal molecular aspects of life (e.g., transcription, translation, and DNA replication), phages too can serve as model organisms for studying universal or at least common aspects of organismal ecology and evolutionary biology. Included are the study of predator-prey interactions, evolutionary optimization of adaptations, the generation of known phylogenies (diverging lineages of evolving populations), genetic constraints on natural selection, and the evolutionary roles played by genetic drift. The advantages associated with employing phages in these studies include their relatively simple biology, their rapid rates of reproduction, the exceedingly high numbers that phages may be grown within relatively small volumes, ease of long-term storage, high mutations rates (especially for RNA and ssDNA phages), ease of laboratory manipulation, amenability to genetic engineering (including reverse genetics, i.e., engineering in mutations), and, perhaps especially, the relative smallness of phage genomes which allows for routine whole-genome sequencing.

Closer Look at Certain Aspects of Phage Biology

Certain aspects of phage biology have been extremely well defined molecularly. In this section we provide an introduction to several of these processes, focusing on phage adsorption, virion assembly, lysis, lysogeny, and phage evolution.

Adsorption

Adsorption describes the process by which phages attach to the surface of host bacteria. This process has been especially well defined for the contractile, long tail fiber-containing T-even bacteriophages. The tips of the six long tail fibers bind to specific surface proteins or other bacterial receptor molecules (such as lipopolysaccharide). It has been shown that three of the six tail fibers are sufficient to properly orient the phage onto the surface of the cell, placing the base plate, found at the distal end of the tail, in proximity to the surface. Binding of the long tail fibers is reversible so that if the base plate is not adjacent to its receptor, then the long tail fibers can release. These reversible interactions allow the phage to “walk” across the surface of the cell until the short tail fibers, found under the phage base plate, are able to successfully bind. Short tail fiber binding is irreversible and, along with the long tail fibers, triggers the opening of the base plate. The remainder of the infection process consists of tail sheath contraction, exposure of phage enzymes that help degrade the cell wall, penetration of the tail tube through the cell envelope to the cell membrane, and subsequent ejection of the phage genome into the bacterial cytoplasm.

Virion Self Assembly

Assembly of the virion particle is often described as “self” assembly because an ordered assembly process has evolved in which complex structures are built by the individual component proteins, which assemble in a defined order, aided by only a limited number of accessory or helper proteins. In addition, different virion components, such as the head, tail, and, if present, the tail fibers, will self assemble independently and then join together. The tail is perhaps the most complex of the three main components and its assembly illustrates several principles. As outlined in Fig. 2, in T-even phages tail assembly begins with the

Fig. 2 T-even phage tail assembly. Self assembly of the phage tail begins as wedge and hub proteins join together to form a partial base plate. Base plate assembly is completed by the addition of the short tail fiber and joining proteins. Two completed base plates (top and side views) are shown. The base plate acts as the assembly initiator for the tail tube. As the tail tube assembles, the base plate/tail tube acts as the assembly initiator for the tail sheath. Once the tail tube and, then, the tail sheath are completed, connector proteins are added. The connector proteins will join the head and tail together after the head is filled with DNA. Note that not all steps are shown and that some steps require accessory proteins that are not part of the final structure. For example, short tail fiber assembly requires a chaperonin, which is a protein necessary for proper folding of another protein into its native conformation. Adapted from Figure 8 of Coombs, D. H. and Arisaka, F. (1994). T4 tail structure and function. In: J. Karam (ed.), *Molecular biology of bacteriophage T4*. Washington, DC: American Society of Microbiology, pp. 259–281.

base plate. This is composed of six wedges that are each made up of several different proteins and hub protein complexes. The wedges and hubs combine to form the hexagonal base plate. Once the base plate has assembled, the short tail fibers attach to it. Only after that step is completed does the tail tube form, assembling onto the base plate. Once the tail tube is formed, then the proteins that make up the contractile sheath assemble around the tail tube. Finally, the tail assembly is completed by the addition of connector proteins that will link the completed tail to the head, after its assembly (including genome packaging) is completed. Over 20 different proteins form the tail, but only two chaperone proteins (proteins that aid protein folding) are needed for tail assembly. In each step of assembly, the partially completed structure acts as the initiating complex for the next proteins to bind to and complete their folding to their final form. A similar process is followed by phage heads and tail fibers.

Filamentous phages, such as M13, have a very different assembly pathway that reflects their chronic release. Because of this type of release, completed virions do not accumulate in the infected cell. Instead, they are continually extruded from the infected bacterium and assembly is intimately tied to this extrusion. Assembly takes place at the cell membrane and all phage proteins that are involved in virion formation, including those involved in pore assembly through which virions are extruded, are integral proteins that collect in the membrane. Virion assembly begins when a phage genome, bound to a specific structural protein at the genome packaging site, enters the pore. Additional capsid proteins attach to the growing virion as it passes through the pore until the entire genome is coated with the major coat protein. The capsid is completed with minor coat proteins binding to the terminus, including the receptor binding proteins. This completion also triggers the release of the now mature virion.

Genome Packaging into Capsids

As part of the self assembly of phage virions, replicated phage genomes must be packaged into phage capsids. This process has been well studied for the tailed, dsDNA phages, which package their DNA into the virion head. The process of DNA packaging is not straightforward owing to the length of DNA that must be packaged along with the need to package that DNA into heads at a density that in many cases is nearly crystalline. Furthermore, the DNA must be packaged in such a way that DNA exits from heads both smoothly and rapidly when infecting a new host cell. This packaging involves enzymes responsible for moving DNA through ports found in what are known, prior to their maturation, as proheads. All tailed, dsDNA phages package their genomes as linear molecules either exactly one genome in length or slightly longer. In both cases the genome is packaged from a large concatemer containing many copies of the phage genome that may be linear or more structurally complex (branched concatemers). Phages that package more than one genome length of DNA package that DNA directly from this concatemer and continue packaging DNA into the prohead until it is full. Hence, it is the capacity of the phage head that determines the amount of DNA that is packaged and the mechanism is described as “headful” packaging. Because there is more than one genome length of DNA packaged, the ends of the linear molecule are duplicated and this duplicated DNA is often used to circularize the genome after the next infection. Furthermore, this mechanism means that each individual phage packages genomes that have different segments of the genome duplicated, resulting in a genomic map that is circular.

Phages that do not package DNA by headful mechanisms often employ genomic elements that determine the ends of the packaged DNA by defining where the genome is cut from the replication concatemer. Hence, these phages package exactly one genome length and the map of that genome is linear. For example, phage λ flanks the ends of its packaged genome with *cos* sites which are over 200 base pairs long and act as recognition sites for the packaging enzymes (terminases) that cleave near the middle of the *cos* sites, leaving a 12 base pair overhang. These ends are recognized by other packaging enzymes that place the DNA into the maturing phage head. The *cos* sites also allow for the λ genome to circularize when infecting the next cell. Other phages use similar packaging-enzyme recognition sites that are more generically described as *pac* sites (for packaging).

Lysis

Phage-induced bacterial lysis serves as a means by which mature phage progeny may be released from phage-infected bacteria. Lysis allows rapid release of large numbers of these progeny, but comes at the expense of ending intracellular phage-progeny production. That is, lytic phages can continue to produce progeny or release those progeny to find new cells to infect, but not both simultaneously, and only in that order. Phage-induced lysis also has the effect of destroying the infected bacterium, which is relevant with regard to nutrient cycling within ecosystems (i.e., the freeing up of nutrients locked within bacteria as well as the release of intracellular bacterial enzymes, and other molecules, which can go on to modify the extracellular environment). The best studied of phage-associated lysis mechanisms involves at least two components, a protein called a holin and a second protein that digests the bacterial cell wall (the endolysin, also known, generically, as a lysozyme or lysin).

The holin controls both the timing of lysis and the access of the endolysin to the cell wall (the cell wall is divided from the cytoplasm, where the endolysin accumulates, by the bacterial plasma membrane). Accumulating in the plasma membrane of the infected bacterium, the holin proteins create holes with precise timing to effect catastrophic exposure of the cell wall to the phage endolysin. For lytic ssDNA phages, by contrast, lysis is achieved via the production and exporting of a cell-wall synthesis inhibitor. As cells continue to grow despite phage replication, these inhibitors eventually cause a cell-wall failure, giving rise to osmotic lysis of the bacterial cell and thereupon release of intracellular phage progeny.

Another type of lysis is lysis from without, which is effected by T4-like phages. In this lysis mechanism, adsorption by multiple phages to a single cell weakens the cell wall, due to lytic enzymes found on the phage tail, contributing to cell wall failure and osmotic lysis of the cell. This mechanism of lysis may serve to augment the lysis of these phages during growth within cultures containing high densities of phage-infected bacteria. The lysis effected by purified phage endolysins, that is, lysins, as applied to bacteria as bactericidal agents is also described as a lysis from without.

Lysogeny

Temperate phages are capable of causing lysogeny. Fig. 3 outlines the relationship of lysogeny as compared to a lytic infection. The prophage is the temperate phage genome as found during lysogeny. Traditionally temperate phages are described as integrating into the host genome, and replicating along with the bacterial genome, as seen with the prototype temperate phage, phage λ . Temperate phages which effect lysogeny by forming plasmids, however, are also known (e.g., phages P1 and N15). Note that temperate phages are not properly described as lysogenic since lysogeny, traditionally, is considered to be a characteristic of bacteria rather than of phage.

Upon infection, temperate phages may be “reduced” to a prophage rather than display a productive infection. Temperate phages such as phage λ (as well as phage P22 and CTX Φ) display a site-specific reciprocal insertion into the host genome. The steps in this mechanism include a closing of the linear phage genome into a circle, which is followed by recombination over small regions of

Fig. 3 Outline of the life cycles of a temperate phage. After infecting, early proteins made by the phage determine whether the phage will enter the lytic or lysogenic modes. In lysogeny, the phage genome forms a prophage, which for most temperate phages is integrated into the host genome. In this state, bacterial replication also replicates the phage genome, thereby maintaining lysogeny. Some change in bacterial metabolism, typically DNA damage that induces the bacterial SOS pathway, triggers the prophage to enter an active state via the process of prophage induction. The prophage is excised from the bacterial genome and begins expressing phage genes, just as occurs with phage infections that instead go directly into the lytic phase. Genes for genome replication as well as virion structural proteins and genome packaging are expressed. The genome is packaged into proheads, virion assembly is completed, and the cell is lysed to release the phage progeny. Note that not all details are shown and that some temperate phages do not follow these specific details.

homology between phage and bacterium at a specific site in the host chromosome. This integration mechanism is catalyzed by the phage integrase enzyme. To go from a lysogenic to a productive state, a process called induction, excision enzymes reverse this integration step. Contrasting phage λ , phage Mu displays a nonreplicative transposition mechanism to insert rather than recombine its genome into the host bacterium in a manner that is similar to that employed by transposons or retroviruses, such as human immunodeficiency virus (HIV). This transposition is not site-specific, unlike phage λ integration, and, as a consequence, results in random mutation by gene disruption of the bacterial chromosome. “Mu” in fact is named for the first two letters of the word “Mutation.”

To prevent induction, which is activation of a productive infection, prophages express repressor proteins that inhibit the transcription of genes necessary for exit from the lysogenic state. In addition to maintaining lysogeny, the repressor protein is responsible for causing immunity (superinfection immunity), which is the inhibition of infection by phage of the same type. For many temperate phages, induction occurs following DNA damage, which induces the bacterial SOS system, leading to repressor inactivation by cleavage.

Mosaic Model of Phage Evolution

The earliest studies of the arrangement of genes in phage genomes showed that these genes tend to cluster by function. For example, most of the virion head protein genes tend to be adjacent to each other within the genome and may even express as a single operon. This has advantages for coregulation of genes of similar function and it also tends to increase the genetic linkage of genes of related function. As more and more phage genomes have been sequenced, it has become clear that genes of related function are often exchanged in blocks via recombination events. This recombination can be illegitimate, and thereby involving no sequence homology among the regions swapped. Alternatively it may involve minimal homology. In addition to the swapping of gene blocks, individual genes, or more rarely even parts of genes may be swapped as well.

These nonhomologous or minimally homologous exchanges are probably fairly rare on a per-infection basis, and most recognizable recombination events likely result in phage genomes that are fatally defective. The large numbers of phages and phage infections that are thought to be present and occur in natural environments, and even to some degree in the laboratory, however, presumably allow for sufficient recombination between divergent coinfecting phages such that gene exchange is a major mode of evolution for bacteriophages despite minimal homology. These exchanges should occur especially during productive phage infections of bacterial lysogens, with recombination occurring between infecting phage and prophage, or among prophages present within a single bacterial cell. The result is that phage genomes typically are mosaic, with different genes or regions found within a phage genome displaying greatest homology with a diversity of different phages.

Homology also is found with bacterial genes but, in many cases, phage genes with no homology to previously characterized gene sequences instead are found. This is seen to a substantial extent during both phage whole-genome sequencing and during the generation of viral metagenomes and suggests that there exists an enormous diversity of genetic information encoded by the world's phages. In addition, regions of genome homology between phage types that otherwise are quite distinctive (e.g., phage T4 and phage λ) are not uncommon.

Overview of Well-Studied Phage Types

A number of phage types have been extensively studied and serve as models for our understanding of phage biology. Among these phages are the famous “T” (for type) phages of *E. coli* B which were assembled by Milislav Demerec with the help of Max Delbrück: phages T1 through T7. We present an overview of these T phages first, starting with the best studied among them, phage T4. We then discuss phage λ , which also is a coliphage, and which serves as the archetypical temperate phage. Then we turn to brief synopses of a number of additional phage types and lastly discuss certain categories of phage types including marine phages, cyanobacterial phages, and phages of mycobacteria as well as archaeal viruses.

Phage T4 (Also T2, T6, RB69, etc.)

Bacteriophage T4 is a well-studied, obligately lytic phage of *E. coli*. It is a member of the family Myoviridae, meaning that it has a contractile tail as well as an icosahedral head. Phage T4 has a relatively large dsDNA genome of approximately 170,000 bases, including modified bases (glycosylated hydroxymethylcytosines) that allow the phage genome to resist digestion by numerous bacterial restriction endonucleases. As one of the best studied of phage types, the biology of phage T4, like that of phage λ , may be considered archetypical. In studies of phage evolution, phage T4 along with phages T2 and T6 form the original members of the T-even family of bacteriophages, which now includes many members that infect many other species of bacteria besides *E. coli*.

Among the interesting, additional characteristics of phage T4 biology are a highly structured self-assembly pathway for virion particles; multiple modes of DNA replication initiation that are utilized at defined times during the replication cycle; a gradual subversion of the host RNA polymerase complex by a combination of covalent modification and replacement of accessory proteins that allows sequential recognition of various classes of phage promoters; rapid breakdown of the host genome and mRNA to supply nucleotides for phage replication and transcription; a large number of nonessential gene products; unusual genetic features including overlapping genes; and the first non-eukaryotic introns identified.

Phage T1 (Also TLS, and Others)

Bacteriophage T1 is another member of the classic seven T phages. It is also an obligately lytic virus of *E. coli*, but unlike T4 it is a member of the Siphoviridae family, having an icosahedral head and a long flexible, noncontractile tail. The T1 genome consists of a single dsDNA molecule of just under 50,000 base pairs. Phage T1 and related phages are less well studied than the T-even family, in part due to T1's early reputation as a troublesome phage: T1 virion particles are notoriously durable and persistent, resistant to desiccation, and able to spread as aerosolized particles, resulting in its reputation as a contaminant. Stories of labs requiring periodic sterilization or hanging ultraviolet lamps abound, as does the (likely apocryphal) story of an early researcher recovering a sample of T1 from the letter sent by a colleague declining to send a sample. While some of these stories may be exaggerated, many commonly used laboratory strains of *E. coli* carry the *tonA* or *tonB* allele, which confers resistance to phage T1 infection.

Phages T3 and T7

Morphologically, T3 and T7 are Podoviridae, possessing an icosahedral capsid with a short tail and tail fibers. The T7 genome is just under 40,000 base pairs of dsDNA. Unlike most phages, the packaged genome only occupies about half of the virion head. The remainder of the space is taken up by a large complex of internal proteins that the genome is coiled around. Packaging of the phage genome is less precise than with other phages, and DNA of between 85% and 103% of the full genome may be packaged. The internal proteins are ejected from the phage head before genome ejection and seem to form a channel through the cell membrane for the genome. Genome entry into the cell is unusually slow for a bacteriophage and seems to require active transcription of the initially entering DNA (850 base pairs) for the remaining genome to enter the cell. It appears that it is transcription itself rather than the expression of particular genes that is the key to phage DNA internalization.

Both phages T3 and T7 produce their own RNA polymerases for late gene expression. These RNA polymerases are unusually specific for the phage promoters and have found widespread use in many commercialized gene expression vectors. Phage T7 has also found use as a phage display vehicle.

Phages T3 and T7 are two members of a larger group of phages related by genomic analysis. Not all members are coliphages but include, for example, phages infecting *Yersinia*, ϕ A1122 and ϕ YeO3-12, and a *Pseudomonas putida* phage, gh-1. These other phages display high degrees of homology to phage T7 genes as consistent with the mosaic model for phage evolution. The host range of phage T7 supports this family linkage: Wild type T7 can infect some species of *Salmonella* and *Shigella* but extended host range mutants that can infect some *Yersinia* species have also been isolated as have some mutants of ϕ A1122 that can infect *E. coli*.

Phage T5

Bacteriophage T5 is an obligately lytic phage of *E. coli* that is classified as a member of the Siphoviridae family, having an icosahedral head and a long, noncontractile tail. Its genome is composed of a single linear piece of dsDNA, just over 121,000 base pairs. Although its life cycle has several unusual features, phage T5 is not nearly as well studied as other phage types considered here. In part this lack of study is due to the presence of a large number of unusually strong promoters that interfere with bacterial metabolism when cloning of genomic fragments is attempted. Among the unusual features are a number of nicks in the packaged genomic DNA and the excretion of nucleotides from the infected cell soon after infection. This excretion ends after the genome has completely entered the cell.

The entry of the phage genome into the cell is also different from most other families of phages in that phage T5 (and a few near relatives) do not eject their entire genomes into the cell at one time. Instead, about 8% of the genome is ejected into the cell. Expression of the genes on this segment are necessary for the remainder of the genome to enter the cell. Ten proteins appear to be expressed from this genome segment, although not all are essential for genome entry. The pause between first stage and second stage genome transfer is about 5 minutes.

Phage λ

Phage λ displays the Siphoviridae morphology, possessing an icosahedral head and a long, flexible, noncontractile tail. Phage λ is the type phage for a large number of related phages usually described as lambdoid and though phage λ infects *E. coli*, other lambdoid phages infect strains of *Salmonella*, *Shigella*, *Pseudomonas*, *Burkholderia*, etc. Though strictly speaking the term lambdoid is reserved for those phages that can form recombinants with phage λ when they enter the same cell, the term also is used more loosely to describe any phage that has the appropriate morphology and a temperate life cycle.

The genome of phage λ is a single dsDNA molecule about 48,500 base pairs long. In its intracellular circular form, the genome can be readily distinguished into a single portion of about one-third of the genome that contains genes related to lysogeny. The other segment, constituting the other two-thirds of the genome, contains structural and other lytic-phase related genes. When the genome is packaged, the lytic phase genes are separated, forming right and left arms of the genome, flanking the central lysogenic segment. The temperate life cycle and lysogenic state are described elsewhere in this entry.

Phage N4

Phage N4 is a member of family Podoviridae which infects a limited number of *E. coli* K-12 strains. Unlike other coliphages, which infect using receptors that are fairly common on the *E. coli* surface, there appear to be only five attachment sites for N4 on each cell.

The N4 genome is a single linear dsDNA molecule of about 70,000 base pairs. The left end of the genome is unusual in that it has a 5–6 base 3′ overhang while the right end varies between substrains and may be blunt or have a 1, 2 or 3 base pair 3′ overhang.

The virion of phage N4 is also unusual, not in its structure, but in its contents. In addition to the phage genome, there are one or two copies of a phage-encoded RNA polymerase, designated ν RNAP. This RNA polymerase is essential for phage N4 early gene transcription. One of those early transcripts is for a second RNA polymerase, RNAPII, which mediates middle gene transcription. Surprisingly, phage N4 late gene transcription appears to be effected by the host *E. coli* RNA polymerase. Even more surprisingly, the phage-encoded ssDNA binding protein, normally employed during DNA replication, is also needed for transcription from late genes.

Phage ϕ 29

Phage ϕ 29 and related phages are Podoviridae that infect the Gram positive *Bacillus* species, especially *B. subtilis*, as well as other especially Gram-positive bacteria. These phages are notable for their relatively small genomes, which are linear, dsDNA, and about 20,000 base pairs long. Phage ϕ 29 has served as a model system for the study of transcriptional regulation, DNA replication, and virion morphogenesis.

Phage SPP1

Phage SPP1 is a well-characterized generalized transducing phage of *B. subtilis* possessing a Siphoviridae virion morphology. It has a linear dsDNA genome of about 44,000 base pairs. Phage SPP1 and related phages are capable of effecting the transduction of plasmids. SPP1 also has been employed to study phage transfection, which is the transformation of competent bacteria with a phage genome leading to infection.

Phage P1

Phage P1 is a temperate phage of the Myoviridae family, possessing an icosahedral head and long, contractile tail. Phage P1 can mediate generalized transduction between *E. coli* strains and other Gram-negative bacteria. In addition to its generalized transducing abilities, phage P1 has two interesting features: First, though a temperate phage, P1 does not integrate its dsDNA genome into the bacterial genome. Instead, the genome circularizes and replicates in a plasmid-like state. The phage devotes several genes to controlling replication and partitioning of the plasmid so that it is stably maintained at low copy number.

Second, phage P1 also has two complete sets of tail fiber genes, each conferring a different host range. These genes are arranged in opposite orientation in the phage genome with a single control region located between. A phage-encoded inversion system switches the control region from one orientation to the other, activating one or the other set of tail fiber genes. Any single burst contains identical progeny. However, during the lysogenic phase the inversion system is active enough so that a population of lysogens will produce about 50% of phage of each host range type. It is this inversion system that has been adapted to create the Cre/Lox recombination system.

Phage P2

Phage P2, like phage P1, is a temperate Myoviridae of *E. coli* and, in fact, both phages were isolated at the same time. The phage P2 genome is a single, linear dsDNA molecule, about 33,000 base pairs in length. Unlike phage P1, phage P2 integrates its genome into the host chromosome during lysogeny and is not particularly efficient at generalized transduction. Phage P2 and related phages, however, do seem to be readily able to capture nonessential genes that have no role in phage metabolism, that is, morons (as described above). These allow the phage to confer lysogenic conversion phenotypes to host bacteria. In addition, these related phages display extensive mosaicism similar to that of the T-even and lambdoid families of phages.

Phage P4

Phage P4 is a satellite phage, only able to productively infect *E. coli* strains that are P2 or related phage lysogens. Viruses that parasitize viruses in other host systems have also been described as virophages although this term is becoming more commonly associated with satellite viruses whose host virus is a virus infecting amoeba. P4 is dependent on the P2 genome for all of its virion proteins. Consequently, morphogenetically phage P4 is also a member of family Myoviridae, although a P4-encoded protein causes the P4 heads to be smaller than normal phage P2 heads. This smaller head size reflects the smaller genome size of phage P4. The linear dsDNA genome is only 11,600 base pairs compared to the over 33,000 base pairs of phage P2.

Phage P4 is also a temperate phage and can form *E. coli* lysogens irrespective of the presence or absence of a phage P2 genome. The P4 genome can exist in the lysogenic state as a multicopy plasmid form or it can integrate into the host genome at a specific integration site, as does phage λ . Because of this dual mode of lysogeny, the genome is sometimes described as a phasmid (phage-plasmid). Alternatively, the phage P4 genome is described by some as a plasmid that uses an especially effective means of transferring between cells: transduction by phage P2. This description also reflects genetic analysis of the phage P4 genome, which indicates that it is not merely a defective form of phage P2 but rather an independently arising phage. It should also be noted that phage P4 is not unique as a satellite phage, although the number of other examples for which a bacteriophage is the host virus is still very small.

Phage N15

Phage N15 is a temperate phage displaying a Siphoviridae morphology of an icosahedral head, and long noncontractile tail. It is quite similar to phage λ in genome size and organization as well. It deviates from the lambdoid life cycle in the lysogenic phase, where the phage genome does not integrate into the host genome or form a circular, plasmid-like form. Instead it remains as a linear episomal element separate from the host genome. It does this by forming a circular intermediate upon entering the cell which is acted upon by a phage-encoded protelomerase that cuts the circular genome and covalently closes each end of the molecule by joining the two strands together. Replication is accomplished in several modes which either involve cutting of one or both of the ends for replication and resealing or which lead to the production of a circular dimer that is cut and resealed as two linear closed-monomer genomes.

Phage P22

Phage P22 is a temperate phage of *Salmonella* that is often described as lambdoid because of its temperate life cycle and similar genetic structure to phage λ . It differs from λ in that phage P22 is a member of family Podoviridae (rather than family Siphoviridae), with adsorption organelles, the tailspikes and a tail needle, attached to a short tail at one of the vertices of the phage head. Also, while λ is a specialized transducing phage, P22 is a generalized transducing phage. Phage P22 and related phages are thought to play important roles in the evolution of pathogenic strains of *Salmonella* and many P22-like phages have acquired genes that make their lysogens more virulent through phage conversion.

Phage Mu

Phage Mu is a member of family Myoviridae, with an icosahedral head and contractile tail. Its packaged genome consists of a single, linear dsDNA molecule with about 37,000 base pairs. In addition, the phage usually packages between 500 and 3000 base pairs of host DNA from random chromosomal locations, making phage Mu a generalized transducing phage. Phage Mu exhibits a temperate life cycle with its genome integrated into the chromosome of its host *E. coli*. It is after integration that the Mu genome displays an unusual alternate mode of movement, acting as a transposon that moves from one location in the host genome to another. It can do this in a nonreplicative manner leaving one location and inserting into another or it can utilize a replicative transfer mode and a second copy of the genome/transposon is created at the second location. Phage Mu is not unique in this dual existence. Mu-like prophages have been found in other bacteria including *Pseudomonas*, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Deinococcus radiodurans*.

In addition to its dual prophage/transposon nature, phage Mu has other notable features including a dual set of tail fiber genes that are differentially expressed in a manner similar to those of phage P1. Each set confers a very different host range: *E. coli* and *Salmonella* strains in one mode and *Shigella*, *Enterobacter*, *Erwinia*, and *Citrobacter* strains in the other. Finally, as a transposon, Mu has been used to modify and study a wide variety of bacterial genomes, many of which phage Mu cannot naturally infect. These range as far from *E. coli* as strains of *Rhizobium* and *Agrobacterium*.

Phages Found in Marine Environments

Marine phages are notable especially in terms of their great numbers and probable impact on marine bacteria. Recently a wealth of information has accumulated on these phages, an exploration that is driven, to a great extent, by the potential impact marine phages have on global carbon cycles as important converters of bacterial biomass into dissolved organic matter. To some degree the phrase marine "phages" is a misnomer, however, as direct counts of virus particles, as marine viruses are often observed, consist not just of bacteriophages but also of archaeal as well as eukaryotic viruses. This is true to a degree as well for marine virus metagenomes (viromes) though many of the resulting sequences are relatively easily classified as bacteriophage-like versus genetically similar to archaeal or eukaryotic viruses.

Cyanophages

Among marine as well as freshwater bacteriophages are many infecting cyanobacteria, once described instead as blue-green algae. Cyanobacteria are bacteria possessing a plant-like photosynthetic apparatus and are responsible for generating a significant proportion of the Earth's atmosphere oxygen. They also are important producers in aquatic systems (that is, photosynthetic fixers of CO₂). Consequently, the lysis of these bacteria by phages (i.e., by cyanophages) redirects much of the resulting organic carbon (and energy) of cyanobacterial photosynthesis from protist predators of cyanobacteria, redirecting it instead into dissolved organic matter (that is, converting intact bacteria into smaller bacterial parts). Dissolved organic matter is mostly unavailable to eukaryotes and instead nourishes especially heterotrophic bacteria which, like cyanobacteria, also serve as prey of phagotrophic eukaryotes as well as of phages. Characterization of cyanophages of the genera *Synechococcus* and *Prochlorococcus* has been especially productive. Among the interesting observations is the encoding by certain cyanophages of proteins that play roles in host-cell photosynthesis during infection.

Mycobacterium Phages

The acid-fast mycobacteria are important disease agents (e.g., tuberculosis) but nonpathogenic mycobacteria are commonly found as soil saprobes. Mycophages, the phages of mycobacteria, are important for their role as molecular tools useful in the study of mycobacteria, especially their genetics. As an offshoot of those efforts, mycobacteriophages serve as a phage cohort that is employed in the study of comparative phage genomics, the study of entire phage genomes. A diverse group of mycophages have been identified as part of the SEA-PHAGES (originally Phage Hunters) program, an educational module used by many college and high school biology programs. This has also led to the identification of new genera of bacteriophages. Clinical roles for mycophages are in phage-based bacterial detection schemes including ones that assess antibiotic susceptibility and for phage therapy of mycobacterial infections.

Archaeal Viruses

The archaea represent one of the three cellular domains of life, the others being the bacteria and the eukaryotes. Typically researchers prefer to not describe the viruses of this lineage as phages, though archaeans are bacteria-like in the sense that the cells of both domains lack cell nuclei. Many archaeal viruses, however, are tailed (just as many or most bacteriophages are tailed), though among archaeal viruses are also a number of morphologies that are quite unlike those found among bacteriophages (Fig. 1). Presumably archaeal viruses play similar roles in archaean ecology as bacteriophages play in bacterial ecology. In addition, there appears to be distant but nonetheless structurally perceptible evolutionary kinship between certain archaeal viruses and bacteriophages.

Introduction

Foodborne pathogenic bacteria are bacteria that contaminate food products with the potential to cause disease, transmitted through the ingestion of the contaminated food. Some of the more prominent bacterial foodborne pathogens include *Listeria monocytogenes*, *Campylobacter jejuni*, *Salmonella* spp. and *Escherichia coli*. Significant costs are incurred as a result of the distribution and consumption of foods contaminated with these bacteria, both in terms of the monetary cost to the food industry and more importantly, in terms of the cost to the wellbeing of the members of the public affected by such a disease outbreak (Zhao *et al.*, 2014).

Of the 864 outbreaks of foodborne illness in the US in 2014, 468 had confirmed or suspected etiology, for which the Centre for Disease Control (CDC) attributes 53% of these outbreaks to bacterial pathogens. *Salmonella* was the most common bacterial causative agent of foodborne disease outbreaks; 140 outbreaks resulting in 2395 illnesses were attributed to the bacterium. *Salmonella* was also responsible for the largest number of hospitalisations (395), whilst *Listeria monocytogenes* that in the US in 2014 was most likely to cause hospitalisation amongst those who had been infected (93%). It was estimated, 17 deaths were caused by bacterial foodborne pathogens, 13 of which were caused by *Listeria monocytogenes* (CDC, 2016). These death rates and rates of infection put a strong impetus on clinical bacteriology laboratories to return a diagnosis to the clinic as rapidly as possible in order to deliver the correct treatment (Gould *et al.*, 2013). Bacteriology results also play a significant role in determining the source of a disease outbreak.

Painter *et al.* (2013) estimated that of the 1451 annual deaths attributed to foodborne illness outbreaks between 1998 and 2008, 862 were caused by bacterial pathogens. 19% of deaths were attributed to poultry, the majority of which had been contaminated by *Listeria* and *Salmonella* spp.

Between 2010 and 2014, 3% of all foodborne outbreaks in the US were said to be multi-state in nature, however, significantly, these outbreaks were responsible for 54% of deaths associated with foodborne disease outbreaks. The most common pathogens associated with multi-state outbreaks were *Salmonella*, shiga-toxin producing *Escherichia coli* (STEC) and *Listeria* species. The rise of the multi-state outbreak is likely due to the centralisation of food production and its wide distribution across many states as well as the demand for ready-to-eat (RTE) foods that do not require cooking. This calls for more stringent food safety practices within the food industry and stricter implementation of quality management systems in food production facilities, with the aim to restrict the size and frequency of outbreaks (Crowe *et al.*, 2015).

In order to achieve the best standards of food safety, new methods that enable rapid, sensitive and specific detection of foodborne pathogens are required. Ideal methods must not be labour intensive, must not require significant levels of expertise and should be portable for use at the point of production. These methods must also be cost effective allowing for regular and reproducible testing at critical control points throughout the production process. Ideally, methods must also be easily adapted to suit different sample matrices (Billington *et al.*, 2014). The aim of this article is to review the current state of the art in rapid bacterial pathogen detection focusing on the potential of bacteriophage derived detection systems compared to the more traditional culture-, antibody and nucleic acid-based methods.

Pathogen Detection Methods

Culture Based Pathogen Detection Methods

Conventional methods for bacterial pathogen detection include culture based screening followed by identification using a variety of biochemical assays. These culture based methods remain the standard to which all newly developed methods are compared due to the high levels of accuracy that can be achieved. Despite being both sensitive and specific for detection of the target pathogen, there are a number of significant issues associated with culture based methods. Perhaps the most significant issue is that culture based methods are very time consuming. This process often involves sample pre-enrichment, selective enrichment and plating on agar plates, followed by the use of standard biochemical analysis for identification of the bacteria present in a sample. This process is laborious and requires a certain level of microbiological expertise and can take at least 2–3 days to get primary results with longer times needed for the identification of the contaminant. This delay between the taking of a sample and the identification of a bacterial contaminant can have major consequences due to the fact that the food from which the contaminant was isolated, may have already been distributed for sale (Law *et al.*, 2014).

This article is a reprint of Alan Cunningham, Katrina Campbell, Olivia McAuliffe, Bacteriophages and Rapid Detection of Bacterial Pathogens: A Novel Approach, *Reference Module in Life Sciences*, Elsevier, 2018.

Culture based methods can lead to the release of negative result for foods that contain viable, but non-culturable cells, as these cells will not be grown during the enrichment process, only growing in their natural habitats when conditions are most suitable. This may lead to the distribution of goods for sale that contain bacterial pathogens (Zeng *et al.*, 2016).

Due to the drawbacks of culture based pathogen detection, other avenues have been explored that have the potential to reduce the time needed to identify contamination in food during the production process. These alternative methods can be grouped into three categories: nucleic acid based methods, immunoassays and biosensors (biosensors usually incorporating aspects of immunoassays or nucleic acid based methods with the addition of a signal transduction platform that allows for signal amplification) (Law *et al.*, 2014).

Nucleic Acid Based Pathogen Detection

Nucleic acid based detection methods usually involve polymerase chain reaction (PCR). The presence of a pathogen is determined by the presence of nucleic acid sequences (DNA or RNA) that are specific to the pathogen in question (Mangal *et al.*, 2016) or by the detection of toxin encoding or virulence genes (Law *et al.*, 2014).

PCR based methods work by amplifying target DNA from the pathogen to a detectable level, thus confirming the presence of DNA from that pathogen in the tested sample. The products of the PCR are then visualised on an agarose gel alongside positive and negative controls, confirming the presence or absence of the target and thus the presence or absence of the bacterial contaminant.

Multiplex PCR is used for the simultaneous detection of more than one pathogen, or multiple strains of the same pathogen in a single PCR reaction eliminating the need for numerous different tests. Kawasaki *et al.* (2009) developed a multiplex PCR system for the detection of extracted *Salmonella* spp., *L. monocytogenes* and *E. coli* O157:H7 DNA from enrichment cultures. The presence of DNA from each of the bacteria is confirmed through the amplification of different sized DNA fragments, with each fragment corresponding to the presence of a different pathogen. In order for multiplex PCR to be successful, all PCR primers must be designed to work under the same conditions to ensure that all of the target bacterial species or strains are detected (Law *et al.*, 2014).

Quantitative real-time PCR (q-PCR) allows for the simultaneous detection and quantification of the target pathogen. In this method the addition of an oligonucleotide that acts as a molecular probe allows for the real time detection of the target DNA. As the target DNA is amplified, the probe fluoresces with levels of fluorescence directly proportional to the number of amplicons. This allows for the enumeration of the original template and therefore the quantification of the number of target pathogens in the initial sample (Mangal *et al.*, 2016). Boehme *et al.* (2010) described a method based on real time PCR for the point of care detection and diagnosis of *Mycobacterium tuberculosis* and its susceptibility to rifampin treatment. The method involved the direct detection of the bacterium from clinical sputum samples. The assay could identify 97% of culture-positive patients in less than two hours.

A third method based on PCR is reverse-transcription PCR (RT-PCR). In this method, RNA acts as the template. This ensures that only bacteria that are actively transcribing their DNA into mRNA are detected, thus lowering the chances of detection of dead cells. This method involves an initial step which uses a reverse transcriptase to reverse transcribe RNA to cDNA. This cDNA then acts as the template similar to a traditional PCR (Sharma, 2006). Senoh *et al.* (2014) described a method that utilised RT-PCR for the detection of mRNA transcripts of toxin-encoding genes from *Clostridium difficile* in spiked faecal samples thus distinguishing vegetative cells from dead cells or spores. The method described has a detection limit of 5×10^2 cfu in a 100 g faecal sample.

An alternative nucleic acid based method of pathogen detection is the DNA microarray. This method involves the immobilisation of DNA probes; oligonucleotides that have sequences that are specific to target DNA from the pathogen in question. Presence of a pathogen is determined by hybridisation between the probes and sample DNA. Microarrays often involve an initial amplification of the target DNA in order to increase sensitivity and eliminate interference from the matrix material (Rasooly and Herold, 2008).

Whilst nucleic acid based methods are useful there are a number of drawbacks associated with them. The need for samples to be enriched before testing can proceed adds at least 24 h to the time that it takes to get a result. Due to the complex nature of these methods, they are not amenable to use at the point of production. The technicalities of the procedures require highly trained personnel to carry them out. This raises questions about the rapidity of these methods (Zhao *et al.*, 2014).

Immunoassay Based Pathogen Detection

Immunological assays for pathogen detection work on the basis of antibody–antigen interaction. The quality of an immunoassay hinges on the level of affinity and specificity of the antibody for the antigen. In the case of the detection of whole bacteria, the antibody must bind to an epitope(s) on the cell surface. The epitope must be unique to the target pathogen in order to ensure assay specificity. Monoclonal antibodies have greatly increased the reliability of immunoassays for pathogen detection by reducing the chances of non-specific binding and thus false positive results (Zhao *et al.*, 2014).

Enzyme-linked immunosorbance assays (ELISA) are amongst the most commonly used immunoassays for pathogen detection. In a method known as a sandwich ELISA, antibodies are immobilised to the surface of the wells of a microtiter plate. The sample to be tested is then added to the wells followed by a subsequent washing. If the target antigen is present it will bind to the antibody and remain bound following the wash step. A secondary antibody that will bind to another epitope on the analyte, usually conjugated with an enzyme such as horseradish peroxidase, is then added and subsequently washed. If the antigen is present the secondary antibody will remain bound to the antigen in the well. The substrate to the enzyme which is conjugated to the secondary antibody is then added resulting in a colorimetric change that is directly proportional to the amount of secondary antibody that is bound and is therefore an indication of the presence of the pathogen. The intensity of the colour can be compared to a standard curve that relates

to known concentrations of the antigen, allowing for the inference of the concentration of the antigen in the test sample (Law *et al.*, 2014). Savolainen *et al.* (2013) used an ELISA for the detection of urinary lipoarabinomannan (uLAM), a component of the *Mycobacterium tuberculosis* cell wall that is dispersed into the urine during cell replication. When urine samples were concentrated 100×, assay sensitivity of 57% was achieved with specificity of 87%.

Lateral flow immunoassays employ immunochromatographic strips through which the sample migrates. If the antigen is present it will first bind to an antibody conjugate such as a colour labelled antibody. It then migrates to a strip of immobilised antibody, which binds to the antigen conjugate. If the antigen is present a colour change will occur at the strip of antibodies. A second strip of antibodies that specifically detect the colour labelled antibody acts as a control, ensuring that there has been adequate migration of the sample as in a pregnancy test (Law *et al.*, 2014). The use of a lateral flow immunoassay has been described for the detection of the *Staphylococcus aureus* virulence factor Panton-Valentine leukocidin (Monecke *et al.*, 2013). The assay used monoclonal antibodies that were generated through phage display with the assay achieving a lower limit of detection of 1 ng ml⁻¹ in *S. aureus* cultures.

Immunoassays experience similar pitfalls to nucleic acid based methods of pathogen detection. Sample enrichment is often required in order to have desired levels of sensitivity resulting in less rapid methods. Some immunoassays such as ELISA require trained personnel to carry them out, increasing costs. Antibodies can become denatured at room temperature and therefore require specific storage conditions in order to maintain their functionality. There are also ethical issues associated with the production of antibodies due to the need to immunise animals with potentially harmful substances (Singh *et al.*, 2013).

All of these methods require sample enrichment. This involves the growth of the pathogen. Due to this proliferation of the pathogen, these methods are not amenable to use at the point of production as it will increase the likelihood of contamination. This means that any diagnostic protocols must be performed at a separate facility to that of production. This further adds to the delay in retrieving positive contamination results, and thus a delay in the implementation of measures that will prevent the distribution of potentially contaminated foods.

Biosensors

Immunosensors

To overcome limitations associated with traditional immunoassays, the concept of antibody-antigen interaction has been exploited for the development of biosensor platforms. Biosensors offer an alternate means of pathogen detection. A biosensor has four key components; a biorecognition element or bio-probe, a signal transduction platform, a signal amplifier and a display, all of which combine to make an automated system that requires little labour. The biorecognition element is responsible for detection. Any binding to the bio-probe is then converted into a signal by the signal transducer. The signal amplifier amplifies the signal to measurable levels and the display provides a read-out of the test results (Fig. 1; Singh *et al.*, 2013). The parameters to be considered when developing a biosensor include assay sensitivity and specificity, the time it takes to get reliable results, the size of the equipment, the extent of the sample preparation and the level of expertise required by the operator (Table 1).

The Biorecognition Element

Perhaps the most important component of a biosensor, the biorecognition element allows for the specific detection of the target. Biorecognition elements that have been used on these technology platforms include antibodies, oligonucleotides, bacteriophages (phage), phage derived proteins and phage display peptides. The method of immobilisation of the biorecognition element can significantly alter the quality of the assay and is therefore usually assessed during assay development (Singh *et al.*, 2013).

Li *et al.* (2015) describe an impedance based immunosensor for the detection of the foodborne pathogen *E. coli* O157:H7. Impedance based biosensors work on the principle of an analyte binding to a bioreceptor resulting in a change in the electron transfer resistance and capacitance on the surface of an electrode (Ahmed *et al.*, 2014). The method described by Li *et al.* (2015)

Fig. 1 A schematic diagram of a biosensor system. (a) A sample is passed over a signal transducer that has been functionalised with a biorecognition element (antibodies or antibody fragments, oligonucleotides, bacteriophage, phage derived proteins or phage display peptides). (b) Where an analyte is present that is recognised by the biorecognition element a binding event will occur. (c) The binding of the analyte will result in the change of a property of the transducer resulting in a measurable signal or the addition of a further reagent that reacts with the analyte, following a wash step, will provide a measurable signal.

Table 1 Ideal properties of a detection system for foodborne pathogens in the food industry

Parameter	Description
Sensitivity	A detection system should be able to detect as few live bacteria as possible
Specificity	A detection system must be able to accurately differentiate target from non-target bacteria
Time	There should be minimal delay between sample receipt and contaminant identification
Size	The detection system should be portable and amenable for use at the point of production
Preparation	There should be minimal sample preparation
Expertise	The operator should require minimal levels of expertise

involves the immobilisation of antibodies on screen-printed interdigitated microelectrodes. The antibodies used bind to an antigen on the bacterial cell surface. This binding event results in a change in the impedance of the electrodes and thus indicates the presence of the pathogen. A detection limit of 10^2 cfu ml⁻¹ was achieved using this method to detect stationary phase *E. coli* O157:H7 in phosphate buffered saline (PBS).

An electrochemical immunosensor for the detection of the uropathogenic *E. coli* was described by Gayathri *et al.* (2016). Uropathogenic *E. coli* is one of the leading causes of urinary tract infections. A detection range of 10^2 – 10^9 cfu ml⁻¹ was observed in cells suspended in phosphate buffered saline (PBS). Clinical applicability of the sensor was tested using artificially spiked urine samples.

Barlen *et al.* (2007) describe the development of an immunosensor that employs a surface plasmon resonance (SPR) based immunoassay for detection of *Salmonella* serotypes. SPR systems use polarised light, which passes through a prism that is in contact with a transducer surface functionalised by the biorecognition element. The binding of an analyte to the biorecognition element results in a change to the refractive index of the transducer thus altering the angle at which the light exits the prism (Ahmed *et al.*, 2014). The method noted above for the detection of *Salmonella* uses an immobilised polyclonal antibody to capture all serotypes followed by specific detection using detection antibodies similar to a sandwich ELISA. The assay was shown to simultaneously detect *Salmonella typhimurium* and *Salmonella enteritidis* at lower limits of 2.50×10^5 cells ml⁻¹ and 2.50×10^8 cells ml⁻¹, respectively.

Whilst antibodies are among the most widely exploited entities for biorecognition in sensor development, there are a few issues associated with their use. There are significant costs associated with antibody production and purification which can drive up the cost of the sensor. Antibodies also have a notoriously short shelf-life resulting in a reduction in binding efficiency and their stability over time. The quality of the biosensor is also dependent on the level of specificity that antibody has for its target antigen. This has led to research into alternative biorecognition elements for detection of foodborne bacteria (Ahmed *et al.*, 2014).

Bacteriophages

The Potential of Bacteriophage Based Pathogen Detection

By their nature bacteriophages (phage) and phage derived proteins have attractive characteristics for exploitation in the detection of pathogens, offering an alternative option to more traditional nucleic acid and antibody based methods (Singh *et al.*, 2013).

Phages are obligate parasitic viruses that infect bacteria with incredible levels of specificity, having co-evolved with their respective hosts; phages have been known to infect their hosts with specificity down to the strain level. They are the most diverse and populous organism on the planet, such has been their success. Phages are divided into two categories; temperate and virulent. In order for both types of phage to reproduce they must first infect their host. The first step in the infection process is host recognition. Receptor binding proteins (RBP) in the phage tail are responsible for the initial phage-host interaction. These proteins bind to a receptor on the cell surface of the host. The receptor is usually unique to that bacterium, conferring the specificity of the phage-host interaction. Upon receptor binding, the phage essentially injects its genetic material into the host cell. It will then employ the host's DNA replication machinery to replicate its genome and the host's translation machinery to translate it into the components that assemble into a whole phage, eventually resulting in the burst of the cell (Fig. 2). Temperate phages may also incorporate their DNA into the host genome where they can remain dormant, replicating and reproducing at a later time (Vinay *et al.*, 2015). Due to their harmlessness to humans and their specific interaction with their host, phages have been exploited by the food industry for both biocontrol and detection of foodborne pathogens in food matrices.

A number of phage based food additives have been approved for use by administrative bodies for the biocontrol of bacteria, harnessing the phage replication cycle for its bactericidal properties. A phage preparation, available commercially as ListShield™ (Intralytix Inc.), consisting of a preparation of six bacteriophages known to infect and kill *L. monocytogenes* cells, was approved by the Food and Drug Administration (FDA) for use in preservation of ready-to-eat (RTE) meats. Listex P100 (Micros Food Safety) is a preparation of a single broad spectrum bacteriophage active against multiple *L. monocytogenes* serotypes, that has been generally regarded as safe (GRAS) by the FDA and is commercially available for use in cheese production as well as other areas of the food industry (Bai *et al.*, 2016). Companies with a focus on phage based biocontrol of bacteria are outlined in Table 2.

Enzyme linked fluorescent assays that employ phage proteins for the detection of a number of pathogens are commercially available under the name VIDAS (bioMérieux). These automated assays offer “next day detection”, requiring a single enrichment step. A comparative study showed that the VIDAS apparatus for the detection of *E. coli* O157:H7 produced comparable results to a

Fig. 2 Schematic diagram of the phage replication cycle. (a) The phage adsorbs to the bacterial cell surface via its receptor-binding protein (RBP). (b) The phage genome penetrates the host cell wall. (c) The phage harnesses the host DNA replication machinery to replicate its own genome. (d) The newly replicated phage genomes are translated and are then encapsulated forming fully assembled phage. (e) The host cell is lysed allowing the newly reproduced phage to adsorb to the surface of other host bacteria initiating the cycle again.

Table 2 Companies producing phage based biocontrol products for the food industry

Company	Statement	Source
EpiBiome	"A substantial opportunity exists for EpiBiome's technology, which provides. . . compatibility with organic production practices"	EpiBiome (2017)
APS Biocontrol Ltd	"Our core technology is based on bacteriophage; . . . and our lead product, Biolyse [®] is a world first; a bacteriophage-based solution for washed and packed fresh produce"	APS Biocontrol Ltd (2017)
Intralytix Inc.	"a biotechnology company focused on the discovery, production and marketing of bacteriophage-based products to control bacterial pathogens in environmental, food processing, and medical settings"	Intralytix Inc (2017)
Micreos	"Micreos has FDA-approved food safety products: <i>Salmonalex</i> [™] against <i>Salmonella</i> and <i>Listex</i> [™] against <i>Listeria monocytogenes</i> "	Micreos (2017)

U.S. Department of Agriculture, Food Safety and Inspection Service reference method, following an 18–24 h enrichment (Savoye *et al.*, 2011). This precedence for the safe use of phage in the food production and food safety environments opens up opportunities for further use of phage in food safety and diagnostics (Sharma, 2013).

The Current State of the Art in Phage Based Pathogen Detection

The idea of using fluorescently labelled phage or phage proteins has been widely exploited for both direct detection and biosensor based detection of bacterial pathogens (Table 3) (Jain *et al.*, 2012; Namura *et al.*, 2008; Vinay *et al.*, 2015; Oda *et al.*, 2004; Schmelcher *et al.*, 2010). Schmelcher *et al.* (2010) developed a method that allowed for detection and differentiation of different strains of *L. monocytogenes* by using different cell wall binding domains (CBD) derived from phage endolysins, tagged with different colour fluorescent markers. Endolysins are enzymes that are produced by phages which catalyse the hydrolysis of the peptidoglycan in the bacterial cell wall, rupturing the cell at the end of the virulence cycle. These proteins have a modular structure consisting of two (or more) distinct domains; most notable are the enzymatically active domain (EAD), which is responsible for lysis, and the cell wall binding domain (CBD) which directs the protein towards its peptidoglycan substrate. The CBDs of phage endolysins have been shown to bind to their respective ligands in the host cell wall with great levels of specificity and have thus been harnessed for use in the detection of Gram positive bacteria that do not have an outer membrane protecting their cell wall peptidoglycan (Schmelcher *et al.*, 2012). Schmelcher *et al.* (2010) exploited a number of CBDs that had different binding spectra in order to differentiate *L. monocytogenes* strains in mixed culture. The different CBDs were tagged with green, cyan and yellow fluorescence proteins as well as RedStar protein, allowing for the visualisation of different strains under different fluorescence microscopy conditions following incubation with the fluorescently tagged CBDs.

Table 3 Examples of phage based methods of pathogen detection

Technology	Detection principle	Organism detected	Detection limit	Sample preparation	Time of analysis	Reference
Reporter phage	Expression of a <i>gfp</i> -tagged high-intensity flourophage	<i>Mycobacterium tuberculosis</i>	N/A	12 h incubation	1 to 2 days (incl. drug susceptibility testing)	Jain <i>et al.</i> (2012)
	Expression of a <i>luxAB</i> -tagged reporter phage	<i>Pseudomonas syringae</i> pv. <i>maculicola</i>	1.3×10^3 cfu ml ⁻¹	120 min incubation	4 h	Schofield <i>et al.</i> (2012a)
	Expression of a <i>luxAB</i> -tagged reporter phage	<i>Listeria monocytogenes</i>	0.1–10 cfu g ⁻¹ (depending on the food matrix)	20 h pre-enrichment	24 h	Loessner <i>et al.</i> (1997)
Tagged phage and phage proteins	Binding of a GFP-labelled phage to the cell surface	<i>Escherichia coli</i> O157: H7	N/A	10 min incubation with GFP tagged phage	N/A	Oda <i>et al.</i> (2004)
	Binding of fluorescently-labelled CBD's to differentiate strains	<i>Listeria monocytogenes</i>	N/A	24 h incl. selective enrichment	N/A	Schmelcher <i>et al.</i> (2010)
	Host mediated biotinylation of phage followed by conjugation to streptavidin coated quantum dots	<i>E. coli</i>	20 cells ml ⁻¹	N/A	1 h	Edgar <i>et al.</i> (2006)

Another means by which phage have been used for detection of pathogens is by harnessing their virulence to make reporter phage. Schofield *et al.* (2012a) developed an engineered bioluminescent reporter phage for the detection of the blight causing bacteria *Pseudomonas cannabina* pv. *alisalensis*, which affects members of the *Brassicaceae* family including significant food crops such as cabbage, broccoli and rapeseed. Bacterial *luxAB* genes, which code for a bacterial luciferase, were incorporated into a *P. cannabina* pv. *alisalensis* specific bacteriophage. The reporter phage conferred rapid and specific identification of the target bacteria through a bioluminescence assay. Bacterial pathogens that affect *Brassica* spp, that were closely related to the target pathogen were not detected or produced a significantly smaller signal when compared to *P. cannabina* pv. *alisalensis*.

Jain *et al.* (2012) describe the development of a fluorescent reporter phage for the detection of *Mycobacterium tuberculosis* in clinical sputum samples. Pre-incubation of these samples with the reporter phage resulted in detection of *M. tuberculosis* by both microscopy and flow cytometry. Additionally this reporter phage was used for drug susceptibility testing of *M. tuberculosis* strains by observing fluorescence levels following antibiotic exposure.

Burnham *et al.* (2014) developed a method that harnesses the lytic activity of the T4 bacteriophage for the detection of *E. coli* in water samples. A recombinant *lac Z* T4 phage which carried the gene for β -galactosidase was used. Upon host lysis, β -galactosidase was released into the media allowing for its detection through the addition of chromogenic or bioluminescent substrates. A detection limit of less than 10 cfu ml⁻¹ was achieved in 5.5 h through the use of the bioluminescent β -galactosidase substrate from the Beta-Glo[®] assay system (Promega).

A method for the detection of the causative agent of anthrax, *Bacillus anthracis*, infamous for its use by bioterrorists, has been approved by the FDA for the detection of the bacterium from clinical samples (Schofield *et al.*, 2012b). The U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID) modified the method that was originally developed by the Centre for Disease Control (CDC) in the 1950s. This method employs γ phage to detect the target bacteria. This phage is highly selective for *B. anthracis* whilst having a very broad host range within the species. *B. anthracis* is identified by zones of clearing on bacterial isolate lawns as a result of exposure to the phage (Abshire *et al.*, 2005).

Phage Based Biosensors for Pathogen Detection

Phages are known to infect their respective hosts with extraordinary specificity. This level of specificity marks them as a great alternative to antibodies and nucleic acids as biorecognition elements for the detection of their hosts on biosensor platforms (Vinay *et al.*, 2015).

Phage based biosensors have shown great promise for the detection of foodborne pathogens (Table 4). Singh *et al.* (2011) harnessed the receptor binding protein (RBP) of the *Campylobacter jejuni* phage NCTC 12673 for the detection of the pathogen. Phage RBPs confer the phage's specificity for its host, binding to unique structures on the bacterial cell surface. The RBP was expressed as a glutathione-S-transferase (GST) fusion protein allowing for its immobilisation on surface plasmon resonance (SPR) surfaces via oriented attachment using glutathione self-assembled monolayers. The principle of surface plasmon resonance, as mentioned previously, is based on the change in the refractive index of the SPR transducer that is in contact with a glass prism, and

Table 4 Examples of phage based biosensors for the detection of bacteria

Detection principle	Organism detected	Biorecognition element	Limit of detection	Reference
Surface plasmon resonance	<i>Staphylococcus aureus</i>	Entact lytic phage	10^4 cfu ml ⁻¹	Balasubramanian <i>et al.</i> (2007)
	<i>Campylobacter jejuni</i>	Phage NCTC 12673 RBP	10^2 cfu ml ⁻¹	Singh <i>et al.</i> (2011)
	<i>Bacillus cereus</i>	Phage PBC1 CBD	10^2 cfu ml ⁻¹	Kong <i>et al.</i> (2015)
	<i>E. coli</i> O157:H7	T4 Phage	10^3 cfu ml ⁻¹	Tawil <i>et al.</i> (2012)
Magnetoelectric Biosensors	MRSA	BP14 Phage	10^3 cfu ml ⁻¹	Tawil <i>et al.</i> (2012)
	<i>Salmonella typhimurium</i>	E2 Phage	1.6×10^2 cfu cm ⁻² (on the surface of egg shells)	Chai <i>et al.</i> (2012)
	<i>Salmonella typhimurium</i>	Gentically engineered phage	N/A	Huang <i>et al.</i> (2009)
	<i>Salmonella typhimurium</i>	Filamentous <i>S. typhimurium</i> phage	10^3 cfu ml ⁻¹	Lakshmanan <i>et al.</i> (2007)
	<i>Bacillus anthracis</i>	Genetically engineered phage	N/A	Huang <i>et al.</i> (2009)
	<i>E. coli</i>	HK620 Phage	10 cfu ml ⁻¹	Vinay <i>et al.</i> (2015)
Impedimetric	<i>E. coli</i>	T4 Phage	10^4 cfu ml ⁻¹	Shabani <i>et al.</i> (2008)

thus the angle of light emitted from the prism. Prior to being subjected to the biosensor a pre-concentration step was done. Capture beads that had the RBP in question immobilised on them were used to concentrate the bacteria from sample solutions. This was necessary due to the low sample volume used on the biosensor platform. A detection limit of 10^2 cfu ml⁻¹ was achieved. Tawil *et al.* (2012) developed a SPR biosensor that uses phage as biorecognition elements for the detection of *E. coli* and methicillin resistant *Staphylococcus aureus* (MRSA). The method that was developed had a detection limit of 10^3 cfu ml⁻¹.

Tawil *et al.* (2012) developed a SPR biosensor that uses phage as biorecognition elements for the detection of *E. coli* and methicillin resistant *Staphylococcus aureus* (MRSA). The method that was developed had a detection limit of 10^3 cfu ml⁻¹.

A phage based magnetoelectric biosensor was developed by Park *et al.* (2013) for the detection of *Salmonella typhimurium* on the artificially inoculated surface of tomatoes. Magnetoelectric biosensors work on the principle of altered resonant frequency of a magnetoelectric resonator upon analyte binding, when said resonator is exposed to an alternating magnetic field. In the case of Park *et al.* (2013) the resonator was functionalised with E2 filamentous phage that specifically targets *S. typhimurium*. Binding of the bacteria to the immobilised phage increases the mass of the resonator thus decreasing its resonant frequency and confirming the presence of the bacterium in the sample. The number of bacteria bound is proportional to the change in mass of the resonator.

Vinay *et al.* (2015) describe a method which employs GFP fusion proteins for the detection of faecal contamination of water through the detection of *E. coli* TD2158 and the successful adaptation of the technique for *Salmonella* detection. The test that was developed involved a 1 h infection with the recombinant phage followed by detection using a portable flow cytometry device. Successful detection of less than 10 cfu ml⁻¹ was achieved in M9 supplemented media. The same detection limit was observed in artificially contaminated seawater.

Chibli *et al.* (2014) demonstrated the use of phage endolysin derived proteins for the detection of *Staphylococcus* spp. and examined their potential for immobilisation on surface plasmon resonance surfaces. This involved the immobilisation of the proteins on PEGylated silicon wafers. These wafers were then immersed in solutions containing fluorescently labelled bacteria. The bound bacteria were visualised by fluorescence microscopy and a detection limit of 5×10^3 bacteria was achieved with the authors noting that this limit may be lower with the use of a signal transduction platform.

Conclusion

Summary

The prevalence of food related disease outbreaks is placing great pressure on the food industry to improve its standards as regards food safety. The demand for convenience foods places a great pressure on manufacturers to ensure that their products are free from contaminants, and that these products measure up to the “ready-to-eat” label that is given to them. Failed detection of bacterial pathogens in food can lead to widely dispersed outbreaks of disease, that have a major impact on public health, to a significant cost to the manufacturer of that food product as well as healthcare services.

The ultimate goal of the food industry is to deliver high quality produce to customers in as fast a time as possible. In order to produce food up to the highest safety standards, food producers must be capable of detecting bacterial contamination in their produce or production facilities in a rapid manner. Bacteriophage offer a novel means to this end. Bacteriophages are (i) specific to their host and therefore may be harnessed for specific detection of that host, (ii) inexpensive to produce and (iii) more robust when compared to alternatives such as antibodies. Whilst phage derived proteins may lack the robustness of whole phage, they remove the pitfalls associated with phage virulence whilst maintaining the advantages that whole phage pose for pathogen detection (van der Merwe *et al.*, 2014).

Receptor binding proteins (RBPs) are responsible for initial phage host interaction and confer the phage's specificity for its host (Kot *et al.*, 2013). This specificity has been harnessed for the purpose of pathogen detection. Developments in the areas of genetic engineering and cloning have allowed for the tagging of RBPs resulting in the ability to orientate immobilisation of the proteins, allowing for greater capture efficiencies during detection (Singh *et al.*, 2013). Cell-wall binding domains from phage endolysins have also been exploited for the detection of Gram positive bacteria. Phage proteins have significant advantages when compared to antibodies. They are less sensitive to fluctuations in environment such as pH or temperature (Singh *et al.*, 2013).

When combined with biosensor technology, bacteriophages have the potential to be a powerful tool in microbiology laboratories in the food industry. Biosensors offer the possibility of rapid screening for bacterial contaminants with the potential to be used by personnel who lack training in molecular or microbiology skills that are required to perform immunoassays; culture or nucleic acid based diagnostic procedures. The portable nature of biosensors makes them amenable to use at the point of production, but only in cases where minimal sample preparation is required.

Bacteriophage Based Diagnostics: Future Prospects

Future research into bacteriophage based diagnostics has the potential to lead to the commercialisation of high throughput biosensor platforms, which are capable of identifying food related pathogens in food matrices in comparably fast turnaround times, when compared to methods that are currently used. The ease of integration of phage and phage derived proteins onto detection platforms, which are already in use with other bioprobes, as well as the precedence for the use of phages as biopreservatives makes them an attractive alternative for use in pathogen detection in the food industry. The broadening of the field of nanobiotechnology occurring in parallel to research into bacteriophages and the mechanisms by which they recognise their hosts, makes for great prospects in the realm of phage based nanodiagnostics.

Glossary

Bottom-fermenting yeasts Yeasts used to produce the type of beer known as lager.

Chill-proofing Use of proteases to prevent haze development when beer is chilled to refrigerated temperatures.

Hops The dried flowers of the female *Humulus lupulus* plant that contribute flavor and antibacterial compounds to beer.

Malt Major raw material used in brewing that provides the appropriate substrate and enzymes needed to yield wort.

Top-fermenting yeasts Yeasts used to produce the type of beer known as ale.

Wild yeasts Yeasts that are present in the brewing process that were not introduced purposely nor tolerated for a specific purpose during brewing.

Wort Liquid that remains after mash is strained, containing soluble fermentable compounds.

Defining Statement

In the brewing of beer, grains are converted through fermentation to produce a desirable beverage with distinct sensory characteristics. This article outlines the steps involved in brewing beer and discusses the variations that can be done to produce the vast variety of beers available.

Introduction

Beer is defined in the Bavarian Purity Law of Germany, as a fermented alcoholic beverage made of malted cereals, water, hops, and yeast. This is the classical definition and has been enforced in Germany since the 16th century. Many countries, however, now allow additional substances to be used in this product. For instance, various enzymes and antifoaming agents are used by some brewers during the fermentation process. Others supplement expensive barley malt with unmalted cereals such as corn, rice, or wheat, which contribute to beer flavor while reducing processing costs.

Beer is generally subdivided into lagers and ales based on its geographic origin and history (Table 1). For centuries, the only beer known to all brewers was ale. During the fermentation of this beer, a thick yeast foam rose to the surface. All too frequently the beer went sour, especially during warmer months. In the 1800s, German brewers observed that if beer could be kept at colder temperatures by brewing in the colder months or by using natural ice or caves, the beer soured less frequently. They also noticed that the yeast settled to the bottom of casks in the cold. This cold-storage method gave birth to “lager” beer in Germany. Lager beers are now traditionally fermented cool and aged cold for several weeks to several months. Ales, on the contrary, ferment at warmer temperatures and are aged only for days. The yeast rises to the surface and is skimmed. Ales have remained the beer of choice in England. The yeast used in lagers and ales have adapted over time to ferment optimally at the temperatures used to produce the respective beer types.

Classic examples of German lager beers are Märzen, Pilsener, Dortmunder, and Bock beer. All these beers are malty with a balance of hoppiness (bitterness). Color can vary from light (Helles) to dark (Dunkel). They usually contain 4.5–5% w/v alcohol, with bock containing 6% w/v. Examples of English ales are bitter, pale ale, porter, and stout. Bitter and pale ale are characterized by a copper color, full body, and elevated bitterness. Porter and stout are dark in color, contain roasted or burnt malts, and may or may not be bitter. Examples of German ales are Weizenbier (wheat beer), Alt, and Kölsch. There are other beer styles that do not clearly fit into the ale or lager category. Most of these beers are Belgian in origin and are spontaneously fermented, for example, Lambic.

History of Brewing

Evidence shows that brewing of beer was a popular practice in Mesopotamia before 3500 BCE. Beers offered people a flavorful alternative to drinking water, were often thought to possess therapeutic properties, and were safer to drink than water in some instances because they were less likely to harbor waterborne pathogens due to the fermentation process. Brewing beer, became

[☆]*Change History:* September 2016. M.A. Harrison and J.B. Albanese Jr.– added co-author; updated some text in the history (including new information on craft brewing) and brewing sections and added sections on gluten-free beer and sour beer and “Further Reading.”

This article is an update of M.A. Harrison, Beer/Brewing, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 23–33.

Table 1 Major beer types

<i>Types</i>	<i>Country of origin</i>
<i>Ales and stouts</i>	
Alt or altbier	Germany
Barley wine	England
Bitter ale	England
Brown ale or mild ale	England
Cream ale	United States
Imperial stout	England
India pale ale	England
Kölsch	Germany
Lambic	Belgium
Porter	England
Saison	Belgium
Stout	Ireland
Sweet stout	England
Weizenbier or wheat beer	Germany
<i>Lagers</i>	
Bock	Germany
Dortmunder	Germany
Dunkel	Germany
Helles	Germany
Malt liquor	United States
Märzen	Germany
Pilsener	Czech Republic
Rauchbier	Germany
Schwarzbier	Germany
Vienna	Austro-Hungarian
Zwickelbier	Germany

popular in other areas of the Middle East, including Ancient Egypt and Israel. Brewing practices had spread to Rome during Caesar's reign and into other parts of Europe. Over the centuries, it was discovered that the addition of hops and other spices would improve the flavor of beer. Since that time, hops have become essential in beer due largely to their contribution to the flavor and stability of beer.

As Europeans settled in North America, they brought brewing practices with them. During the 16th and 17th centuries, breweries were established in Virginia and New England. Barley did not prosper in the New England climate, so a variety of unusual ingredients were fermented, including pumpkins, maple sugar, persimmons, and apples. Two factors contributed to the further development of the North American brewing industry. Pennsylvania was found to be a good barley and hop production area, and the immigration of Germanic and Dutch brewmasters bolstered the American industry.

During this entire period, brewing was basically a hit-or-miss process. Individuals experienced in brewing recognized that using old brewing vessels yielded better products than new ones. It is now realized that the cracks, crevices, and pores present in the older vessels, but lacking in the newer ones, harbored the yeasts and bacteria responsible for the fermentation. Several theories were developed in the 19th century in an attempt to explain the changes that occur during fermentation. Much of the debate centered on the issue of whether fermentation was a purely chemical process or a biological process. The issue was largely settled by Louis Pasteur in the 1860s and 1870s, when he published reports (eg, "Etudes sur la Biere") concluding that fermentation was due to the actions of yeast.

In 1883, Emil Christian Hansen established the method of using pure yeast cultures to produce beer at the Carlsberg Brewery in Copenhagen, Denmark. He had demonstrated previously that the culture used in brewing was often a mixed culture and that the metabolism of wild yeasts caused many of the defects in improperly processed beer. Over the next several years, the practice of using pure yeast cultures to produce beer became more widely accepted. The purpose and function of yeast enzymes in the fermentation process was shown by Buchner in 1897. It was found that cell-free extracts contained enzymes that could ferment sugars.

Today beer remains a popular and profitable beverage. While beer is consumed worldwide, on a per capita basis, the leading beer consuming countries are the Czech Republic, Ireland, Germany, Austria, and the United Kingdom. While US per capita beer consumption in 2002 was about half of that consumed by the leading European countries, it was greater than the volume of milk and bottled water consumed in the country. In that same year, beer sales in the United States exceeded \$60 billion. While US beer production is dominated by two major brewing conglomerates, there has been an explosion in the number of small breweries producing the product, often using traditional methods. These smaller operations are typically labeled as microbreweries.

The beer industry is in the midst of major changes, and nowhere is it more noticeable than with the American craft brewer. Since 2007, the total number of US breweries has grown from 1460 to more than 4600. From 2008–15, production by the largest macrobrewers declined by 23 million barrels. The decline has been attributed to small and independent brewers who in 2016

earned over \$22 billion of the \$105.9 billion US beer industry. With craft beer in America gaining market share from macrobrewers, big brewers have begun acquiring these once small and independent brewers in an attempt to gain back the market share they have lost. With these mergers and acquisitions, the definition of American craft beer as we know it is changing.

The Brewers Association defines an American craft brewer by three pillars: *Small*, *Independent*, and *Traditional*. The brewer must have an annual production of six million barrels or less, have less than 25% of the brewery owned or controlled by a beverage alcohol member that is not itself a craft brewer, and have a majority of its total beverage alcohol volume in beer whose flavor is produced from traditional or innovative brewing ingredients and fermentation. This definition encompasses, brewpubs, microbreweries, regional craft breweries, and contract brewing companies.

As craft beer has taken hold in America, it has created its own culture spreading to different areas of the food and beverage industry. The coinage of “craft” as a moniker to describe a business is now used to separate small, independent entities from large companies. Such is the case with craft maltsters, craft hop growers, and craft distillers.

Brewing

The conversion of cereals into beer is not a direct process. The cereals used in beer production do not contain sufficient quantities of fermentable sugars. These cereals must first undergo modification during the malting and mashing steps to yield carbohydrates that yeast can convert during the fermentation step into ethyl alcohol and carbon dioxide. Freshly produced beer can then be aged for flavor development before it undergoes finishing steps which can include filtering, pasteurization, and packaging. Each of these steps is examined more closely in the following sections and are shown in Fig. 1.

Ingredients

The basic ingredients in beer are water, malted cereals, hops, and yeast. Water comprises 90–95% of the content of finished beer, and its quality can influence the flavor of beer. Barley is the most common cereal used in the Americas and Europe to produce malt, although small volumes of beer are made from other cereal grains. Better beers are produced with clean barley that was properly dried after harvest (to about 10–12% moisture content). Overheating barley during drying can lead to its becoming unacceptable for malting, since its germination potential is adversely affected. Barley contains a high starch content suitable for conversion to fermentable carbohydrates and a sufficient protein content to support yeast growth and contribute to forming beer foam. In addition, it contributes unique flavor components. Hops are the dried flowers from the female hop (*Humulus lupulus*) plant and contribute flavor and antibacterial compounds to beer. Yeasts are the predominant fermentation organisms used to make beer worldwide. In some instances, bacteria may contribute certain characteristics to some regional beers. Malt adjuncts, such as corn, rice, wheat, sorghum grain, soybeans, cassava, potatoes, sugars, and sirups, may be used in some formulations. The adjuncts are all starch- or sugar-containing substrates that contribute fermentable carbohydrates. They also contribute flavor characteristics to produce distinctive varieties of beers. Although enzymes other than those in the malt and those contributed by the yeast are not needed to produce beer, some brewers use additional enzymes to impart desired characteristics to their product.

Malting

The main objective of malting is to produce an ample supply of enzymes that degrade starch, proteins, and other components of grain. The subsequent enzymatic changes provide fermentable sugars from starch and substances needed to support yeast growth (eg, amino acids and fatty acids) from the other substrates. Malt also is a major contributor to the final color and body characteristics of the finished beer. To produce malted barley, barley grains are first steeped in 10–15°C aerated water and then germinated at 15–20°C for 3–7 days. During this time the moisture content increases to approximately 45%. After the barley germinates, the sprouts are removed, leaving a medium rich with α -amylase, β -amylase, proteases, and their respective substrates. The malt is dried and kilned, under controlled conditions that remove the water without inactivating the desired enzymes, to approximately 5% moisture and ground. The flavor of the finished beer can be influenced by the amount of nonenzymatic browning and heat-generated flavor compounds that are formed during the drying process. Dark beers are made using darker, more flavorful malt while less roasted malt is used to brew paler beers. Grinding exposes the starchy endosperm of the grain, which makes the carbohydrates more available.

Mashing

During the mashing step, most of the nonsoluble, unfermentable carbohydrates and proteins are hydrolyzed into soluble fermentable materials, by the enzymes present in the malt. To accomplish this, the ground malt is mixed with water and placed into a mash tun. To enhance α -amylase action during the initial mashing period, the temperature of the mixture is maintained between 40 and 50°C. After a period of time, the temperature of the mix is increased to 65–70°C to enhance β -amylase activity. Within a few hours, the process is complete, and the temperature is increased to at least 75°C to inactivate the enzymes.

While the amylases are active, they degrade the starch contributed by the grain. Dextrins are produced by the action of the α -amylase. The β -amylase splits off the disaccharide, maltose, from the amylose portion of the starch. The products that result from

Fig. 1 Brewing process.

the action of the two amylases known as dextrins also undergo additional enzymatic changes. Branch linkages of the amylopectin portion of starch are broken by de-branching enzymes while amyloglucoside removes single glucose residues from the dextrins. Alterations in the color are also noted (changing from light to dark amber) during mashing.

The normal pH of malt is approximately 5.8 and is not acidic enough for optimum enzyme activity. To achieve optimum activity, the pH can be reduced to approximately 5.2 for lager production. The pH is adjusted to be more acidic for ale production. Adjustment of the acidity, if desired, can be accomplished by addition of acid, usually lactic acid, or by bacterial fermentation. Although the lactic acid bacteria usually are undesirable contaminants, *Lactobacillus delbrueckii* has been used to accomplish this pH reduction in the past. This thermophilic bacterium converts sugars to lactic acid efficiently at temperatures of 42–51°C. Because the variety of microorganisms that can grow at these temperatures is small, it is easier to maintain a pure culture bacterial fermentation as well as to reduce the possibility of contamination by other microbes. Processors may find, however, that the bacterial modification requires much greater supervision and, if not controlled, may contribute to beer spoilage.

After the naturally occurring and any added enzymes are inactivated, the solids settle out, leaving the wort. Wort contains the soluble compounds including the fermentable sugars and longer, nonfermentative oligosaccharides and is separated from the solids before it is transferred into the brew kettle. The spent grain can be used in animal feed. The blend of grains used and the degree of enzymatic activity will influence the composition of the wort. These differences are some of the factors contributing to the characteristics noted in beers from different breweries.

Wort Processing, Hop Addition, and Kettle Boil

After the wort is transferred into a heating tank, called the brew kettle, hops are added to the wort before the mixture is boiled. The boiling of the wort serves several functions: (1) nearly all the microorganisms remaining after mashing are killed, (2) inactivates enzymes remaining after mashing, (3) enhances extraction of essential oils and resins from the hops, (4) substances responsible for cloudiness are precipitated, (5) enhances color development, (6) undesirable volatiles are removed, and (7) water is evaporated and the wort is concentrated. The wort is boiled for 1–2 h.

Hops provide flavor and aroma compounds as well as some compounds, which possess antimicrobial activity. Bitterness is the principal flavor of note. Among the compounds extracted from the hops are essential oils humulone (α -bitter acid), lupulone (β -bitter acid), and tannin. Humulone and lupulone provide important flavor characteristics and also have some antimicrobial properties. The wort is then separated from the spent hops, cooled rapidly, and placed into a fermentation vessel. The spent hops may be used as fertilizer.

Fermentation

At this point in the process, the wort is inoculated with brewers' yeast and fermented. During fermentation, the yeast produces alcohol, carbon dioxide, and some additional flavor constituents. The inoculation step is also called by other names, such as pitching and seeding.

The fermentation room must be maintained in a clean manner to reduce possible contamination problems, and it should be kept at a constant temperature and humidity to maintain the desired growth rate for the yeast. Fermentation vats can be glass lined or constructed of wood, stainless steel, or aluminum. Wooden vats pose problems in cleaning and disinfecting that are not experienced with vessels made of any of the other materials.

The strain of yeast used depends on what type of beer is desired. Lagers are produced using bottom-fermenting yeasts, whereas ales are produced using top-fermenting yeasts. These yeasts have traditionally been referred to as *Saccharomyces pastorianus* (formerly *Saccharomyces carlsbergensis*) and *Saccharomyces cerevisiae*, respectively (Table 2).

The temperature of fermentation for lagers produced by the bottom-fermenting yeasts is usually in the range of 6–15°C and takes 2–7 days. During fermentation, the yeasts tend to flocculate and settle to the bottom of the fermentation vat. These yeasts can be collected from the bottom of the vat for reuse in subsequent fermentations. By varying the fermentation temperature, slightly different versions of lagers can be produced. The fermentation process is exothermic so the fermentation tanks must be cooled.

Ales are traditionally produced using top-fermenting yeasts and incubation temperatures of 18–27°C for 5–7 days. These yeasts tend to form small clumps of cells that are carried to the top of the fermenting liquid and adsorbed to bubbles of carbon dioxide. These yeast cells can be collected from the surface for reuse with the next fermentation batch.

Table 2 Comparison of *Saccharomyces cerevisiae* used to make ales and *Saccharomyces pastorianus* used to make lager yeasts

Characteristic	<i>Saccharomyces cerevisiae</i>	<i>Saccharomyces pastorianus</i>
Flocculation	Clumps or flocs entrap CO ₂ ; lower density floc; floc rises to the surface of the liquid in the fermenter	Higher density floc; floc settles to the bottom of the fermenter
Minimum growth temperature	15°C	7°C
Optimum growth temperature	>30°C	<30°C
Maximum growth temperature	40°C	34°C
Ability to sporulate	Some	No

Since the mid-1800s, the use of bottom-fermenting yeasts in closed fermentation vessels has increased worldwide. A corresponding decrease has occurred for top-fermenting yeasts in open fermentation vessels. In recent times the advantages of the closed fermenter have given rise to “bottom-fermenting” ale strains. These strains maintain the ale flavor characteristics and can be harvested from the bottom, eliminating the need for an open vessel and the risk of contamination.

Regardless of the type of beer made, a rapid decrease in pH during the fermentation will increase its stability and decrease potential problems of contamination. After fermentation, the pH of most lagers decreases from approximately 5.2–5.3 to approximately 4.1–4.2, and it decreases slightly more in ales. These acidic pHs assist in preserving the final product by inhibiting bacterial growth.

Maturation and Conditioning

At the end of fermentation, the “green beer” is separated from the sediment and transferred to wooden (eg, oak) or glass-lined steel tanks. In traditional brewing, maturation of the beer occurs during storage at 0–2°C for several weeks. Lagers are normally aged for slightly longer periods of time than ales. This step allows the beer to develop its final flavor, color, and body characteristics. Many brewers include a short conditioning period after fermentation. Conditioning can be done at temperatures of approximately –1°C for at least 3 days. Clarification occurs to some extent as the yeasts, unstable proteins, and other suspended solids precipitate. Chemical changes occur, which create a more mellow and smooth flavor.

Finishing

Next, beer undergoes several processing steps in preparation for distribution to the consumer. Some of these steps are optional, and some of the steps can be done by a variety of methods. The choice of the brewer depends on what type of finished product is desired. Most beers will be chill-proofed by the addition of proteases to prevent haze development by residual proteins when the product is kept at refrigerated temperatures. Most will also be clarified and filtered to remove remaining solids. The final carbon dioxide level will be adjusted to 0.45–0.52%. The most common carbonation method is to add carbon dioxide back into the product. An alternative way is to add freshly yeasted wort to the beer and allow a natural secondary fermentation. Packaging for beer includes cans, bottles, barrels, and kegs.

To increase the shelf life of canned or bottled beer, it is usually pasteurized. The majority of beer in the past several decades has received heat pasteurization (eg, 62°C for up to 20 min). Beer flavor can be adversely affected if the product is overheated. Thus, there has been and continues to be an interest in using an alternative pasteurization method. One alternative is to flash pasteurize the beer at 71–75°C for 15–30 s before aseptically filling containers. “Cold pasteurization” offers some advantages, such as less flavor loss due to heating and better energy efficiency. Cold pasteurization involves the use of chemical agents for preservation or filtration (“cold filtration”) through membrane filters followed by aseptic packaging. Beer packaged in barrels or kegs may or may not be pasteurized. If it is not pasteurized, it must be chilled and stored under refrigeration temperatures to maintain maximum quality. Typical shelf life is approximately 1 month. If heat- or filter-sterilized, then the shelf life can be up to 3 months.

Beer Properties

A myriad of beers are produced by different brewers. Properly brewed beers have flavor, color, and body characteristics dictated by the ingredients and yeast strain used, wort composition, and conditions for fermentation, aging, and finishing. Among the metabolites produced are ethanol, carbon dioxide, ethyl acetate, other esters, fusel alcohols, diacetyl, 2,3-pentanedione, various sulfur compounds, and amino acids and nucleotides from yeast cells. The type and proportion of these and other compounds in beer contribute the characteristics to a particular brew.

Beers also possess factors that aid in preservation of the product. Properly fermented and packaged beer has alcohol produced during fermentation, a relatively low pH, and a low redox potential, which inhibit a variety of spoilage microorganisms. Some compounds extracted from hops are inhibitory to Gram-positive bacteria.

Acetic acid bacteria, lactic acid bacteria, coliforms, and wild yeasts often contaminate improperly processed beers. Growth of most contaminating microbes in beer is inhibited by the preservation factors associated with the product. For example, the anaerobic environment within the packaged beer inhibits the growth of the aerobic acetic acid bacteria. Coliforms are inhibited when the pH level of the beer is 4.3 or lower.

Properties of Brewing Yeasts

***Saccharomyces* Characteristics**

The genus *Saccharomyces* is composed of ascosporogenous yeasts that produce ovoid, spherical, or elongate cells. *Saccharomyces* strains used in commercial brewing are polyploid species. Reproduction by vegetative means occurs by multilateral budding, whereas sexual reproduction involves the formation of an ascus containing one to four spores. Members of this genus ferment sugars vigorously. Those strains that can yield significant amounts of ethanol by this metabolism are useful commercially.

This genus is a rather diverse group. Some of the growth characteristics for the species *S. cerevisiae* include minimum a_w for growth of 0.90; minimum, optimum, and maximum temperatures for growth of 0–7, 20–30, and 40°C, respectively, and minimum and optimum pH for growth of 2.0–2.4 and 4.0–5.0, respectively.

The taxonomic classification of the yeasts commonly referred to as brewers' yeasts has been debated for many years. According to the most recent taxonomic references, both bottom yeasts and top yeasts are members of the genus *Saccharomyces*. It is estimated that there are probably more than 1000 strains of *Saccharomyces*. Although the differences between strains are usually minor, they may be important to individual brewers. In older literature, the bottom yeasts were widely recognized as *S. carlsbergensis* and later as *S. carlsbergensis* (*uvarum*) or *Saccharomyces uvarum*. Today the species is known as *S. pastorianus*. The old names are still part of the terminology of the brewing industry. Top yeasts are referred to as *S. cerevisiae*.

Factors Affecting Growth of Brewing Yeasts

During brewing, the goal is to maximize the production of desired metabolites of yeast growth while minimizing production of undesirable compounds and yeast biomass. By properly controlling various factors that influence yeast behavior, the brewer can achieve the desired end product. Factors that influence yeast metabolism include wort composition, oxygen level in the wort, inoculation rate, condition of yeast at pitching, the level of microbial contamination, wort pH, and temperature during fermentation. In addition, fermentation can be influenced by the fermenter design and whether a batch or continuous process is used. For example, there is evidence that continuous fermentation may be faster than batch fermentation and may reduce problems associated with handling the yeast culture.

Yeasts growing in batch fermentations use the individual sugars in wort in a sequential order. Sucrose is the first used, followed by glucose, fructose, maltose, and maltotriose, although not all strains can fully use maltotriose efficiently. Ethanol and flavor compounds are among the compounds produced by carbohydrate metabolism. This metabolism also provides the energy to maintain yeast growth. Yeasts also utilize the 19 amino acids normally present in wort in an orderly fashion. The metabolism of the amino acids is needed to maintain yeast nutrition and to contribute flavor to the product.

Strain Development

Throughout the centuries, brewers have searched for yeast strains that will provide the best quality beer in an efficient manner. In the past, this has often been done by screening for the most suitable strain by trial and error or by forming hybrids of two strains with different desirable qualities and screening for a progeny strain with the desired capabilities. Not only are these methods time-consuming, but also the resulting yeast may have both desirable and undesirable qualities from both parental strains. For example, substrate utilization may be improved, but flavor traits may be adversely affected. Recently, use of molecular methods such as recombinant DNA techniques to improve yeast strains has become an option. The advantage of using the molecular methods is that alterations of single characteristics can be accomplished specifically.

The brewing industry is interested in modifying yeast behavior to accomplish several goals, including increasing the efficiency of fermentation, by modifying the uptake and metabolism of wort components, improving the control of fermentation (eg, the timing of late fermentation or yeast flocculation properties), and overall organoleptic quality of beer, developing new beers, and improving the value of by-products (eg, spent yeasts).

Modification of some of these traits using molecular methods has been investigated with some success. Although some of these altered strains have been developed experimentally, currently there are few, if any, used in full-scale commercial operations. In an effort to produce "light" beers less expensively, strains have been developed that ferment more of the carbohydrates present in wort not fermentable by the normal strains. This alleviates the expense of using added enzymes to degrade these carbohydrates.

A second modification that has been accomplished concerns the degradation of α -glucan. This substance causes filtration problems and forms precipitates and hazes in beer. Since use of genetically developed yeast can solve this problem, the expense of using an added enzyme to do the job is eliminated.

Strains with improved proteolytic capabilities have also been developed. These strains reduce the need to use added proteases to degrade the proteins in beer that are responsible for the haze that can develop when finished beer is refrigerated.

Spoilage Problems of Beer

Range of Problems

Concern regarding the transmission of pathogens via beer is rare. In this aspect, beer is unlike most other food and beverage items. The lack of pathogen-related problems is due to the nature of the ingredients, processing methods, and characteristics of the final product.

Spoilage problems, however, can occur. A diverse group of microorganisms can present problems at various stages of brewing (Table 3). The type of spoilage and the microorganisms responsible are influenced by the stage of processing and the characteristics related to the stage. Characteristics that affect spoilage include pH, alcohol content, the types of ingredients, the oxygen level of the product at particular stages, and the level of sanitation within the brewing environment. Wort just prior to fermentation is a rich medium for supporting microbial growth and is extremely susceptible to spoilage.

Table 3 Spoilage problems in beer and the causative microorganisms

Microorganism	Stage of processing encountered	Problem
<i>Lactobacillus</i> spp.	Any stage	Off-flavors Haze Ropiness Acidification
<i>Pediococcus</i> spp.	Inoculation Fermentation Aging	Off-flavors Haze Ropiness Acidification
Acetic acid bacteria	Open fermenters Packaging	Off-flavors Haze Surface pellicles Ropiness
<i>Hafnia protea</i>	Wort Fermentation	Off-flavors Acidification
Other Enterobacteriaceae	Wort	Off-flavors
<i>Bacillus</i> spp.	Wort	Off-flavors
<i>Zymomonas</i> spp.	Packaging	Off-flavors
<i>Pectinatus</i> spp.	Packaging	Off-flavors
<i>Megasphaera</i> spp.	Bottled beers with pH >4.1 and <3.5% ethanol	Off-flavors
Wild yeasts	All stages	Off-flavors Haze
Killer yeasts	Fermentation	Death of desired strain Off-flavors
Molds	Raw barley spoilage	Gushing Off-flavors

Bacterial Spoilage

Lactic acid bacteria

Species of *Lactobacillus* are among the most frequent and troublesome spoilage microorganisms of beer. They can cause spoilage problems at all stages of processing and even in the finished product. The lactobacilli can tolerate hop substances that are inhibitory to many other Gram-positive bacteria. Several species can spoil beer. Among these are those that grow relatively fast during the fermentation step, *Lactobacillus plantarum* and *Lactobacillus brevis*, and those that grow slower, *Lactobacillus lindneri*. A variety of flavor and appearance defects can be produced depending on the metabolic products that the particular spoilage organism produces. For example, *L. brevis* can produce acetic acid in addition to CO₂, ethanol, and lactic acid. Other lactobacilli species that have been noted as problems in beer include *Lactobacillus casei*, and *L. delbrueckii*.

Several lactic acid bacteria species can produce diacetyl in beer. Diacetyl is a chemical that produces a buttery flavor that is undesirable in beer. In addition to the diacetyl-producing *Lactobacillus* species, *Pediococcus acidilactici*, *Pediococcus inopinatus*, and *Pediococcus damnosus* are responsible for this defect. *P. damnosus* is probably the most notable of these and is a continuing concern for brewers. This lactic acid bacterium, like the lactobacilli, is resistant to the inhibitory substances in hops. Some strains of this species can tolerate up to 10% (w/v) ethanol.

Acetic acid bacteria

Species of *Acetobacter* and *Gluconobacter* can spoil beer primarily by converting ethanol to acetic acid. These bacteria are aerobic and are usually only associated with spoilage of beer exposed to air. The increased use of anaerobic conditions in modern breweries has decreased the frequency of problems related to these microorganisms.

Enterobacteriaceae

Although conditions suitable to support growth of most members of the Enterobacteriaceae are relatively few during the processing of beer, there are opportunities for some species to pose problems. The main concern is spoilage of wort before the decrease in pH and accumulation of ethanol that occurs during fermentation. Most enterics stop growing during early fermentation when the pH of wort decreases to <4.4 and when the ethanol content becomes >2% (w/v). Species of *Escherichia*, *Aerobacter*, *Klebsiella*, *Citrobacter*, and *Obesumbacterium* have been reported to cause spoilage problems.

Sporeformers

Although *Clostridium* species may be present on the raw ingredients of beer, these sporeforming microorganisms present no serious spoilage problems in the liquid phase once production commences. Spoilage of spent grains by *Clostridium* has been reported.

Bacillus species, however, have been encountered in spoiled beer. Since most, if not all, of the species within this genus are sensitive to hop components, the spoilage bacilli tend to be more problematic in the stages before the addition of hops to the wort.

Anaerobic gram negatives

Species of three genera of anaerobic, Gram-negative bacteria have been recognized as spoilers. *Zymomonas* was first described in the 1930s in Britain. The occurrence of spoilage problems due to this bacterium elsewhere in the world is rare. This organism produces hydrogen sulfide and acetaldehyde in beer.

Pectinatus and *Megasphaera* species were both described for the first time in the late 1970s. Both are unique to the brewing industry. *Pectinatus* species produce acetic acid, propionic acid, and hydrogen sulfide in beer, whereas species of *Megasphaera* produce primarily fatty acids and hydrogen sulfide.

Other bacteria

Species of *Achromobacter*, *Alcaligenes*, *Flavobacterium*, *Acinetobacter*, and *Pseudomonas* are some of the other bacteria that have been associated with infrequent cases of beer spoilage. Many of these miscellaneous spoilage organisms are aerobic, intolerant of acid environments, and die once fermentation starts. Thus, the problems they can cause are limited to the mash and early wort stages.

Fungal Spoilage

Wild yeasts

Wild yeasts include any yeasts that are present in the brewing process that were not introduced purposely or tolerated for specific purposes in the development of the desired product. There are probably more than 40 species that could be considered within this group. Commonly encountered genera include *Brettanomyces*, *Candida*, *Debaryomyces*, *Hansenula*, *Kluyveromyces*, *Pichia*, *Rhodotorula*, *Torulaspora*, *Zygosaccharomyces*, and other *Saccharomyces* species. Problems due to wild yeasts include the production of undesired flavor compounds, including esters, acidic and phenolic substances, and fatty acids. They may also ferment the product beyond the desired end point, due to their ability to ferment carbohydrates, that the desired brewing yeast cannot utilize. Detection and identification of wild yeasts are important to brewers if they are to recognize the problem and take corrective action. Identification methods vary from biochemical classification to genetic methods, including DNA fingerprinting and gene probes.

Killer yeasts

Killer yeasts can produce a toxic protein, or zymocidin, that adversely affects the plasma membrane of other yeast species or strains. Members of several yeast genera are capable of producing this compound, including some *Saccharomyces* species. The major problem is the death of the desired fermentative yeast strains caused by the toxic protein. Thus, the product is not properly fermented. It has often been noted that killer yeasts can also produce phenolic off-flavors. Spoilage problems due to killer yeasts can occur in either batch or continuous fermentations but tend to be more common with the continuous process. This may be due to the slightly lower pH encountered in the early stages of continuous fermentation.

Molds

Mold contamination of barley is common by a variety of species; thus, it is important to handle barley properly to prevent spoilage prior to malting. Barley spoiled by *Fusarium* can adversely affect the malting process and can cause a problem known as "gushing" in the finished product. Gushing is the sudden release of carbon dioxide when a bottle or can containing beer made from mold-spoiled barley is opened.

Nonmicrobial Chemical and Physical Problems

Skunky and stale beer are two chemical-related problems that can occur. Sunlight-induced photooxidation can result in skunky beer which is most noticeable in clear glass bottled beer. This problem can be avoided (or skunk-proofed) by using reduced forms of iso- α -acids from hop extracts. These compounds are more light-stable and nonreactive. Stale beer is a problem that develops over time during storage. The best way to avoid this problem is to limit the amount of oxygen present in the stored product. Shelf life of the finished product is determined largely by the onset time of staleness.

Haze and foam instability are two physical problems that can occur. Proteinase treatment can reduce the haze problem due to proteins, while β -glucanases degrade β -glucan-containing polysaccharides. Foam stability can be improved by increasing the viscosity and surface tension by adding proteins, gums, and hop components.

Spoilage Control

Controlling spoilage problems in the brewing industry is largely a matter of using the proper sanitation practices. Maintaining a clean, sanitized brewing environment will greatly reduce potential problems related to most of the environmental contaminants. Use of good quality water not only in the beer but also during cleaning and sanitizing is critical.

Using the proper processing practices is also important. Care must be taken to maintain the purity of the yeast strain or strains used by a brewer. The brewer should ensure that the raw ingredients are of good quality and that the processing steps proceed as

expected. It is also important for a brewer to be able to identify contamination problems early, so corrective action can be taken and damage minimized.

Other Types of Beer Processing

African Beers

The native beers of Africa have different ingredients and are brewed differently than the typical European or American beers. Rather than using barley in the malting step, sorghum, millet, or maize are used depending on the geographic location within Africa and the customary practice. Brewing in Africa originated in the home for personal or ceremonial uses, although it later expanded into commercial production. Fermentation of these beers is a two-stage process. First, lactic acid fermentation softens the malt proteins, reduces the pH sufficiently to limit growth of bacterial pathogens, regulates starch conversion to sugar, and contributes to the body of the beer. The second step is yeast fermentation that is initiated just prior to packaging the product. During distribution, there is an active yeast fermentation.

The finished product is unhopped with sour yogurt-like taste, has a pinkish-brown color, and normally contains 2 or 3% alcohol. It is opaque due to the high concentration of suspended solids and yeast cells. This product is actually thought of as a food rather than a beverage. These beers are highly susceptible to spoilage and have a shelf life that is usually less than 5 days. This limited shelf life is due to the wort not being boiled coupled with the fact that the final product characteristics (eg, pH and alcohol content) are not sufficient to limit the growth of acid-tolerant spoilage bacteria.

Home Brewing

It is possible to brew beer at home that may be of similar quality to that of commercially produced beers. Many supply stores sell the necessary ingredients and equipment, although normal kitchen utensils can be used for some of the needs. The processing steps that are used in home brewing are basically the same as those used commercially. There are naturally some limitations to home brewing that the commercial breweries are able to overcome. For example, in home brewing, excess yeast is usually not removed to the same degree and the storage temperature is usually not controlled as well to limit extended fermentation that can occur after packaging. Several books describe home brewing in detail.

Light Beer

Light beers, which were introduced to the market in the 1970s, are made by reducing the unfermentable dextrin content in wort before fermentation occurs. The enzyme glucoamylase is added to the wort to hydrolyze most of the dextrins to glucose. During fermentation the yeasts are able to ferment the glucose to alcohol. Thus, the amount of carbohydrates present that could contribute to the caloric content of the product is decreased, typically by approximately one-third. Simply watering-down regularly brewed beer would reduce the alcohol and caloric content of the beer, but the resulting product would be undesirable due to the diluted flavor and texture components.

Ice Beer

In the 1990s, ice beers attained a degree of popularity. In making ice beers, the fermented beer is chilled down to -4°C to allow for the formation of ice crystals. Removing the crystals reduces the water content and results in a slight increase in the sweetness and alcohol concentration of the finished product.

Dry Beer

Like ice beer, dry beer also became somewhat popular in the 1990s. Dry beer is less sweet than conventionally brewed beer and has less flavor, color, and body. It is made by using less malt and more readily fermentable adjuncts.

Nonalcoholic Beer

Nonalcoholic beers must contain less than 0.5% ethanol. In producing these beverages, ethanol is removed from fermented beer. Various methods are available including distillation, evaporation, dialysis, or reverse osmosis. Using the last two options that are done at low temperatures (less than 10°C) results in the retention of desirable flavor volatiles without the formation of undesirable heat-generated off-flavors.

Wheat Beer

By combining wheat malt with barley malt, a beer that has a thinner body and is more sour in taste than conventionally brewed beers can be made. Wheat beers have a higher phenolic content and is often cloudy in appearance.

Gluten-free Beer

Due to dietary restrictions of those affected by Celiac disease, gluten-free beer has become an option for those who cannot tolerate the protein. Gluten-free beer can be produced by either sourcing gluten-free sugar or starch or by modification of gluten-containing sources. Enzymatic modification is necessary when attempting to make gluten-free beer with normal brewing ingredients. One such way is with the use of a proline-specific endoprotease such as Brewer's Clarex. Such a technology will cleave the immunoreactive epitopes of gluten so as to cause no reaction in the body.

Sour Beer

The term "sour beer" is a blanket term used to describe many types of fermentations and styles. The history of brewing before the isolation of brewing yeast strains and the advent of sanitation is vast with wild and spontaneously fermented beers; most of which had sour qualities. In fact, many classic styles such as Gose, Berliner Weisse, Belgian Oude Bruin, Flanders Red, and Lambic beers contained bacterial and wild yeast qualities [1]. In modern craft brewing, brewers have implemented a variety of methods to achieve flavorful, sought after acidity in their final product.

Lactic acid producing *Lactobacillus* is one of the most common microbes used to sour beer. Its beer spoiling capabilities have been previously mentioned, but used by a skilled brewer, *Lactobacillus* can yield desirable acidity. The quickest use of *Lactobacillus* to gain acidity is in the brewhouse via wort kettle souring. To utilize this method, pre-boil non-hopped wort is kept at a temperature optimal to the *Lactobacillus* strain the brewer chooses to use. Total acidity is monitored by the brewer until the desired acidity is achieved. After the preferred sourness level is reached, wort is boiled with hops added, killing the *Lactobacillus*, and normal beer production commences.

Most sour beer programs involve secondary fermentation due to the yeast *Brettanomyces* or by bacteria such as *Lactobacillus*, *Pediococcus*, and *Acetobacter*. Where *Lactobacillus*, *Pediococcus*, and *Acetobacter* fermentations produce the common acidic notes, flavors derived from *Brettanomyces* fermentation are usually characterized as "funky," with barnyard, earthy, and musty notes. All of these microbes can be inoculated in wooden barrels or tanks post primary fermentation and then blended after aging to produce the desired product.

Some modern brewers use *Brettanomyces* in place of *Saccharomyces* for primary fermentation. When used, a large pitch of the yeast is needed in order for completion of fermentation in a normal production period. Higher levels of aeration will lead to higher production of acetic acid, but lactic acid will not be produced.

Biocides

Marta Ribeiro, University of Porto, Porto, Portugal

Lúcia C Simões, University of Porto, Porto, Portugal; University of Minho, Braga, Portugal

Manuel Simões, University of Minho, Braga, Portugal

Introduction

Biocides have been extensively used in the control of bacteria for decades, and are commonly incorporated into a variety of products including disinfectant formulations, cosmetics, preservatives, pesticides and antiseptics (McDonnell and Russell, 1999; Paulus, 2012). The Directive 98/8/EC of the European Parliament and of the Council of 16 February 1998, concerning the placing of biocidal products on the market, provides a harmonized definition for biocides. Accordingly, biocides are classified as active substances and preparations containing one or more active substances, put up in the form in which they are supplied to the user. These are intended to destroy, deter, render harmless, prevent the action of, or otherwise exert a controlling effect on any harmful organism by chemical or biological means. However, the term biocide is commonly used as synonym of antimicrobial agent or disinfectant/sanitizers. Gilbert and McBain (2003) differentiated and defined the three independently: Biocides (active substances that above certain concentrations and defined conditions will kill cells within specified times); Antimicrobial agents (active substances that have adverse effects on the growth or survival of microorganisms); Disinfectants/sanitizers (formulations containing active substances that are safe for the application to inanimate surfaces and which kill specified groups of disease-producing microorganisms within specified times). The Directive 98/8/EC furthermore states that a biocidal product should obey to the following characteristics: (i) Sufficiently effective with no unacceptable effects on the target organisms (i.e., resistance or cross-resistance); (ii) no unacceptable effects itself or as a result of its residues, on human or animal health, directly or indirectly (i.e., through drinking water, food or feed, indoor air or consequences in the place of work) or on surface water and groundwater; (iii) no unacceptable environmental effect itself, or as a result of its residues (i.e., its fate and distribution in the environment; particularly contamination of surface waters, groundwater and drinking water; its impact on non-target organisms); (iv) its physical and chemical properties have been determined and deemed acceptable for purposes of the appropriate use, storage and transport of the product. In terms of biocide diversity, chemical classification and possible applications, the books of Wypych and Wypych (2015), Rossmore (1995), Paulus (2012), and the Russell, Hugo and Ayliffe's Principles and Practice of Disinfection, Preservation and Sterilization book (Fraise et al., 2013) provide an excellent amount of information.

The excessive use of biocides has considerable environmental and economic impacts and the misuse of more aggressive biocides and increased doses (as a way to overcome the resistance phenomena) constitutes an extra risk to public health. These measures can lead to the selection of pathogens insusceptible to the main available antimicrobials (Russell, 2004). Antimicrobial resistance is even more significant when cells are embedded in a biofilm. Therefore, novel biocides are required for effective disinfection. Phytochemicals (molecules from the plant secondary metabolism) are an unexploited source of novel biocides (Gomes et al., 2016; Malheiro et al., 2016). This chapter describe major biocides in current disinfection practices, with particular emphasis on industrial disinfection, and provides information on the role of phytochemical as a promising source of novel biocides.

Cleaning and Disinfection

The operations of cleaning and disinfection are essential parts of any process affected by microbial contaminations (Carpentier and Cerf, 1993). For instance, on industrial food processing equipment cleaning is an important stage for minimizing microbial colonization (Carpentier and Cerf, 1993; Meireles et al., 2016; Simões et al., 2010). It seems to be of fundamental importance to eliminate as many microorganisms as possible before applying a disinfectant. In the industry, cleaning procedures should effectively remove food debris and other soils that may contain microorganisms or promote microbial growth. Most cleaning regimes include removal of loose soil with cold or warm water followed by the application of chemical agents, rinsing, and disinfection. High temperatures can reduce the need for physical force (Carpentier and Cerf, 1993; Maukonen et al., 2003). Chemical agents, usually surface active agents or alkali compounds, used as detergents, suspend and dissolve food residues by decreasing surface tension, emulsifying fats, and denaturing proteins (Maukonen et al., 2003). These chemical agents are currently used in combination. Many situations, require the occasional use of acid cleaners to clean surfaces soiled with precipitated minerals or having high food residue/mineral content. Mechanical action, particularly water turbulence and scrubbing, are recognized as being highly effective in removing biofilms (Chmielewski and Frank, 2003; Maukonen et al., 2003). An effective cleaning procedure must break up or dissolve the biofilm extracellular polymeric matrix so that the biocide can gain access to the viable cells (Carpentier and Cerf, 1993; Gibson et al., 1999).

The cleaning process can remove around 90% of the surface colonizing microorganisms, but cannot be relied upon to kill them. Bacteria can redeposit at other locations and, given time, water and nutrients can form a new biofilm. Therefore, disinfection must be implemented (Gibson et al., 1999).

This article is a reprint of Marta Ribeiro, Lúcia C. Simões, Manuel Simões, *Biocides, Reference Module in Life Sciences*, Elsevier, 2018.

Disinfection is the use of products (disinfectants) to destroy microorganisms. Nevertheless, microorganisms have been found in disinfectant solutions, which is due to their ability to acquire resistance and build-up protective biofilms (Simões et al., 2011). This means that microbial contamination can be spread on the surface to be disinfected instead of being disinfected.

In food plant operations, disinfection is required, since wet surfaces provide favourable conditions for the growth of microorganisms (Maukonen et al., 2003; Meireles et al., 2016). The aim of disinfection is to reduce the surface population of viable cells after cleaning and prevent microbial growth on surfaces before restart of production. Disinfectants do not penetrate the biofilm matrix left on a surface after an ineffective cleaning procedure, and thus do not destroy all the living cells in biofilms (Carpentier and Cerf, 1993). Disinfectants are more effective in the absence of organic material (fat, carbohydrates, and protein based materials). Interfering organic substances, pH, temperature, water hardness, chemical inhibitors, concentration and contact time generally control the efficacy of biocides (Cloete et al., 1998; Mosteller and Bishop, 1993). The biocides must be effective, safe and easy to use, and easily rinsed off from surfaces, leaving no toxic residues that affect the sensory values of the product. The use of biocides in food plants depends on the material used and the adhering microorganisms. The biocides to be used should be chosen based on the following statements (Troller, 1993; Wirtanen, 1995; Wirtanen et al., 2000):

- Is effective in the pH range used?
- Is stable when diluted?
- Is toxic, safe or irritating?
- What is the microbial spectrum?
- How does the temperature affect the activity?
- Is corrosive at the surface?
- Is surface active?
- Is stable when reacting with organic material?

Table 1 resumes the properties of disinfectants commonly used in industrial systems.

Table 1 Properties and uses of biocides

Type	Applications	Limitations	Comments
Aldehydes	Neutral/alkaline conditions Non-corrosive to all materials Water treatment/slime control in can/ bottle warmers, tunnel pasteurizers Glycol and sweetwater systems in dairies Conveyor lines	Slower, less active under acid conditions Absorbed by porous materials	Broad spectrum kill Toxicity at high concentrations
Amphoteric surfactants	Neutral/alkaline conditions Applicable to all materials Food contact surfaces Environmental areas Spray, manual soak Fog air Foam is suitable for external surface disinfection	Reduced activity under acid conditions Selective germicidal activity Residual film affects cheese starter cultures Used at high concentrations Moderate to high cost Moderate to high foam	No odour/taste carryover Low toxicity Non-irritating
Anionic surfactants at acid conditions	Acid conditions, < pH 3 Carbon dioxide atmosphere Stainless steel, plastics Foam on external surfaces CIP, spray, soak, manual Carbon dioxide atmosphere Overnight disinfection Milkstone/beerstone removal	Effective only at low pH Neutralized by detergent residues Corrosive to soft metals, mild steel Some products moderate to high form upon circulation	Moderate to high foam production Stable at high temperature No odour/taste carryover More costly than halogens
Chlorine	Neutral/alkaline conditions Stainless steel Food contact surfaces Floors/walls/air CIP, spray, soak, fog	Acid conditions High temperature Soft metal; mild steel Vapor phase corrosion	Broad spectrum kill Organic Cl less corrosive Taste/odour carryover Irritates eyes, skin, etc. Environmentally unfriendly Cheap
Chlorine dioxide	Water treatment/slime/odour control	Stabilized form slower and less active under alkaline/neutral conditions	Acidified form is broad spectrum

(Continued)

Table 1 Continued

<i>Type</i>	<i>Applications</i>	<i>Limitations</i>	<i>Comments</i>
Hydrogen peroxide	Rinse for fruit/vegetables	More active acid form requires activating acid and mixing step	Does not form chloramines or trihalomethanes
	Acid form on food contact surfaces	More expensive than chlorine	Uncertain corrosion properties
	Stainless steel	Hazards of generating gas	
	CIP, spray, soak	Irritates human tissues	
Iodine	Applicable to all materials	Weak germicidal properties	Safe decomposition products, water and oxygen
	Sporicide at high concentration at high temperature	Efficacy at high temperatures/high concentration	
	Aseptic packing of beverages	Destabilized by metal contaminants (copper, iron)	
	Acid conditions, < pH 3	Less effective than chlorine	Broad spectrum kill
Isothiazolinones	Stainless steel, plastics	Activity declines rapidly above pH 5	Organic soil reduces efficacy
	Food contact surfaces	Corrosive to soft metals and mild steel	More costly than chlorine but effective at lower concentration
	Floors/walls	Stains certain plastics	
	CIP, spray, soak, manual	Potential taste/odour carryover	
Peracetic acid	Hand disinfectant	Most foam upon circulation	
	Carbon dioxide atmosphere		
	Helps dissolve mineral deposits		
	Acid, alkaline, neutral conditions	Slowly active	Broad spectrum kill
Phenolics	Applicable to all materials	Use on non-food contact surfaces	More active under acid conditions
	Cooling water/towers, can/bottle warmers		
	Long-term, continuous activity		
	Conveyor lubricants		
Polymeric biguanides	Acid conditions	Corrosive in presence of chlorine ions	Broad spectrum kill
	Carbon dioxide atmosphere	Concentrate causes burns, irritations	Safe decomposition products
	Stainless and mild steel, soft metals, plastic, rubber	Pungent odour	Concentrate should not contact mild steel, soft metals
	Food contact surfaces	Rapid decomposition at high temperatures, generates gas and heat	No phosphates;
Quaternary ammonium compounds (cationic surfactants)	CIP, spray, soak	Rapid decomposition by metals, organic matter	Moderate cost
	Lubricants for conveyor lines; Water treatment	Variable germicidal activity	
		Toxicity	
		Irritates body tissue	
Quaternary ammonium compounds (cationic surfactants)		Readily absorbed by many materials	
		Unpleasant odours	
	Acid/alkaline conditions	Limited activity	Activity reduced by organic soil
	Applicable to all materials	Incompatible with anionic surfactants	
Quaternary ammonium compounds (cationic surfactants)	Food contact surfaces	Moderate to high cost	
	Environmental areas		
	Can/bottle warmers, water treatment		
	Spray, soak, manual, circulation		
Quaternary ammonium compounds (cationic surfactants)	Fog air		
	Neutral/alkaline conditions	Selective germicidal activity	Properties vary among different QAC's
	Applicable to all materials	Residual film affects cheese starter cultures	Effective for wetting and penetrating soils
	Food contact surfaces	Moderate to high foam upon circulation	Effective in presence of organic soils
Quaternary ammonium compounds (cationic surfactants)	Environmental areas/residue can extend activity	Toxicity at high concentrations	Non-irritating
	Mildew and odour control	Neutralized by certain surfactants	Newer QAC's have high water hardness tolerance
	Water treatment		
	Spray, soak, manual, circulation

(Ed.), Handbook of Biocide and Preservative Use. Springer, pp. 315–333. Wirtanen, G., 1995. Biofilm Formation and its Elimination from Food Processing Equipment. VTT Publications, p. 251.

Mode of Action of Biocides

The processes involved in the antimicrobial action comprise transportation of the antimicrobial agent to the surface of the cell, adsorption, diffusion, penetration and interaction at the target site. These processes are not instantaneous, the time they take, and the correspondent killing time may differ within antimicrobial agents. The differences also depend on the mode of action, as well as on the chemical constitution and chemical–physical properties of the biocide (Paulus, 2012).

An antimicrobial effect can be defined as an interaction between an active substance and specific targets of the microbial cell. Critical governing features of these interactions are the physicochemical characteristics of the biocide, cell morphology, and the physiology status of the microorganism (Denyer and Stewart, 1998).

Biocides derive from a variety of chemical classes (Table 1). The precise mechanisms of interaction often reflect this diversity, although the final damage outcomes may show considerable similarity. Typical antibacterial events include (Denyer and Stewart, 1998; Araújo et al., 2011):

- Disruption of the transmembrane proton motive force leading to an uncoupling of oxidative phosphorylation and inhibition of active transport across the membrane
- Inhibition of respiration or catabolic/anabolic reactions
- Disruption of replication
- Loss of membrane integrity resulting in leakage of essential intracellular constituents
- Lysis
- Coagulation of intracellular material

Factors Influencing the Efficacy of Biocides

The efficacy of the application of a disinfection procedure is the result of the correct application of an efficient biocide. That means that lack of efficacy may have multicausal explanations and resistance is only one of them. There are some reasons to cause loss of efficacy in a disinfection process which may be misunderstood as resistance. They can be summarized as follows (Bessems, 1998; Heinzel, 1998; Russell, 2003; Simões et al., 2010):

- Use of an inefficient product, i.e., a biocidet which has an incomplete spectrum of activity. By this way all microorganisms which are outside the range of product efficiency will survive and eventually develop resistance to the specific antimicrobial and to related or unrelated molecules (cross-resistance).
- Application of the product without regard to the correct conditions as recommended by the supplier. This concerns mainly concentration, pH, temperature, and time of application but also inactivation by organic matter or other products.
- The prolonged application of biocides at sublethal concentrations may provoke the adaptation of microorganisms to the biocide and possibly to others.
- Insufficient contact of the biocide with the microorganisms.
- Insufficient availability of the biocide.

All these circumstances may diminish the expected action of biocides.

Nevertheless, the main reasons for the failure of a disinfection procedure are linked to the development of microbial resistance. According to Gilbert and McBain (2003), resistance is a description of the relative insusceptibility of a microorganism to a particular treatment under a particular set of conditions. For biocides, it is usually quantified as the concentration that cause sublethal effects on the population cells. Besides the environmental factors, resistance to biocides can be a natural property of a microorganism (intrinsic) or acquired by mutation or acquisition of plasmids – self-replication, extrachromosomal DNA or transposons – chromosomal or plasmid integrating, transmissible DNA cassettes (Cloete, 2003; Gilbert and McBain, 2003; McDonnell and Russell, 1999; White and McDermott, 2001).

Mechanisms of Cellular Resistance to Biocides

Reduced Susceptibility Associated With Genotypic Changes (Acquired Mechanisms)

Reduced susceptibility of microorganisms to biocides may be acquired through mutation, or by the acquisition of a plasmid or transposon (Forbes et al., 2017; Møretro et al., 2017). Chromosomal gene mutations conferring resistance to antibiotics are relatively well-studied (McDonnell and Russell, 1999; White and McDermott, 2001). By contrast, fewer studies have been performed to determine whether mutation confers resistance to biocides (McDonnell and Russell, 1999). In fact, the advances on this topic are modest (Forbes et al., 2017). The mutation that alters the target site of an antimicrobial agent, which acts at specific sites within the bacterial cell, is likely to cause resistance. These mechanisms of resistance are observed through the existence of bypass in the bacterial ribosome or a metabolic enzyme, or overproduction of the target enzyme or of an efflux pump (Beumer et al., 2000).

Acquired resistance arises *via* mutation or as result of the acquisition of genetic elements – plasmids, transposons (White and McDermott, 2001). Acquired, nonplasmid-encoded resistance may result when bacteria are trained to grow in gradually increasing

concentrations of a biocide, although, resistance is not always stable. Temporary resistance by phenotypic adaptation is known, but is considered that, in general, a nongenetic adaptative type of resistance is unlikely to play an important role in determining the long-term survival of bacteria to biocides (Russell, 2001).

Intrinsic Properties of Microorganisms Conferring Reduced Susceptibility

Intrinsic insusceptibility is a natural property of a microorganism and is shown by bacterial spores, mycobacteria, and several Gram-negative bacteria. Gram-negative bacteria are generally relatively less susceptible to antimicrobial agents than Gram-positive bacteria because their cell walls present a more significant barrier to entry (McDonnell and Russell, 1999). The outer membrane of Gram-negative bacteria acts as a permeable barrier because the narrow porin channels limit the penetration of hydrophobic molecules and the low fluidity of the lipopolysaccharides leaflet slows down the inward diffusion of lipophilic compounds (Cloete, 2003; McDonnell and Russell, 1999). Mycobacteria, which possesses a waxy envelope that inhibits the uptake of some antimicrobial agents, are even more resistant (McDonnell and Russell, 1999). The coat and the cortex of bacterial spores present a barrier to the entry of antimicrobial agents, explaining their relatively extreme insusceptibility (Cloete, 2003; McDonnell and Russell, 1999).

When spores germinate, the biochemical and structural changes result in the germinating cells becoming more susceptible to the action of some biocides (Beumer et al., 2000). So, intrinsic microbial resistance is frequently associated with cellular impermeability imparted by the outer layers of a bacterial cell that limit the uptake of antimicrobial agents, although active efflux pumps appears to be an important process (Cloete, 2003; Gilbert and McBain, 2003; Russell, 2001). Efflux is increasingly implicated as a resistance mechanism. Efflux pumps contribute to the intrinsic resistance of Gram-negative bacteria by pumping out a variety of agents, including dyes, detergents and antibiotics (Cloete, 2003). Efflux pumps are recognized as common membrane components in all cell types, from prokaryotes to superior eukaryotes (Van Bambeke et al., 2003). It confers bacteria a common and basic mechanism of resistance by extruding toxic molecules (Cui, 2004). In the context of antibiotic resistance, the term multidrug resistance (MDR) is used to describe a situation where reduced susceptibility to an antibiotic is associated with reduced susceptibility to other chemically unrelated antibiotics through an efflux mechanism. There is evidence that *Pseudomonas aeruginosa* can efflux triclosan and that this represents an important intrinsic susceptibility to bisphenol (Chuanchuen et al., 2001). The presence of the efflux systems coupled with the narrow porin channels in the outer membrane of the cell which restricts diffusion of antimicrobial agents into the cells is responsible for the very high intrinsic resistance of Gram-negative bacteria to antimicrobial agents (Cloete, 2003).

As well as impaired uptake or increased efflux, some microorganisms demonstrate intrinsic resistance through the inactivation of antimicrobial agents (Beumer et al., 2000). Some bacteria can degrade antimicrobial agents (Gilbert and McBain, 2003; Nishihara et al., 2000) and this phenomenon does not appear to be any plasmid involvement, representing another example of intrinsic insusceptibility.

Physiological (phenotypic) adaptation of microorganisms that reduces susceptibility to antimicrobial agents in response to environmental changes is also considered as intrinsic resistance (McDonnell and Russell, 1999). The cell phenotype expressed can vary significantly depending on the environmental conditions under which it is grown (Russell, 2003; White and McDermott, 2001). The resistance of these microorganisms to antimicrobial agents may derive partly from changes in outer cell layers that increase the barrier properties and prevent access to their site of action, but other changes are also involved (Cloete, 2003; McDonnell and Russell, 1999; White and McDermott, 2001). The association of microorganisms with solid surfaces leads to the formation of a biofilm, with bacteria in different zones of the biofilm experiencing different nutrient environments and displaying different physiological properties (Brown and Gilbert, 1993; Gilbert et al., 1990; McDonnell and Russell, 1999). Reduced susceptibility of bacteria in biofilms to antimicrobials can sometimes be extreme and is probably caused by a variety of factors including nutrient depletion within the biofilm, reduced access of the antimicrobial agent to cells in the biofilm, chemical interaction between the chemical agent and the biofilm, and the production of degradative enzymes and neutralizing chemicals (Brown and Gilbert, 1993). Biofilms have been reported as possessing susceptibilities towards biocides and antibiotics that are 100–1000 times less than equivalent populations of planktonic bacteria (Simões, 2011).

Mechanisms of Biofilm Resistance

There is no one answer to the question of why and how bacteria growing in a biofilm develop increased resistance to antimicrobial agents. In the following statements it will be described some of the possible mechanisms accounting for the resistance of bacteria within biofilms.

Resistance and the Extracellular Polymeric Matrix

It has been suggested that the extracellular polymeric matrix, among other functions, prevents the access of biocides to the cells embedded in the biofilm community due to the presence of a charged, hydrated exopolymer matrix around individual cells and microcolonies (Mah and O'Toole, 2001). Restricted diffusion from the surrounding medium, by a combination of ionic interaction and molecular sieving events, may occur for appropriate classes of molecules (Costerton et al., 1987). The constituents of the biofilm matrix act as would an ion exchange resin and actively remove strongly charged molecules (Gilbert et al., 2002). Total penetration failure will only occur when the reaction sites are sufficient to deplete the bulk concentration of the biocide or

replenishment of the matrix proceeds at a faster rate than does adsorption/reaction and diffusion (Stewart et al., 1998). Diffusion limitation studies have generally focused on antibiotics rather than biocides and upon medically relevant biofilm populations rather than biofilms in industrial situations (Stewart, 1996).

In addition to the potential of the biofilm matrix to react directly and chemically quench reactive moieties, retention of enzymes with the capability to inactivate biocides within the biofilm matrix will amplify its barrier properties with respect to the diffusion of suitable substrates (Araújo et al., 2014; Heinzl, 1998).

Resistance Associated With Growth Rate and Nutrient Availability

When a bacterial cell culture becomes starved for a particular nutrient, it slows its growth. Transition from exponential to slow or no growth is generally accompanied by an increase in resistance to biocides (Lewis, 2001; Wentland et al., 1996). Because cells growing in biofilms are expected to experience some form of nutrient limitation, it has been suggested that this physiological change can account for the resistance of biofilms to antimicrobial agents (Mah and O'Toole, 2001; Stewart and Franklin, 2008). Desai et al. (1998) compared the resistance of planktonic and biofilm cells at different stages during exponential growth up to the entry into stationary phase. They found that resistance increased as the planktonic cultures and the biofilm cells approached stationary phase. The maximal resistance of both cultures occurred in stationary phase where the biofilm cells were about 15 times more resistant than the planktonic cells. These results suggested that some determinant other than growth rate is responsible for a certain level of resistance and slow growth adds additional protection (Fux et al., 2005).

Oxygen gradients within the biofilm may also directly influence the activity of some biocides (Gilbert et al., 2002). Another phenomenon is the existence of physiological gradients across biofilms on growth and metabolism of cells at the periphery, to consume nutrients before they permeate to the more deeply placed cells. The peripheral cells will have growth rates and nutrient profiles that are similar to those of planktonic cells, allowing for the existence of heterogeneity within biofilm. Advances in technology have resulted in the ability to visualize the heterogeneity within a biofilm (Fux et al., 2005). The environmental heterogeneity that exists within a biofilm might promote the formation of a heterogeneous population of cells, such different levels of resistance can be expressed throughout the community (Fux et al., 2005; Wentland et al., 1996). So, a major contributor towards the inefficacy of biocides when applied to biofilms must, therefore, be associated with physiological heterogeneity (Mah and O'Toole, 2001; Simões et al., 2011).

Resistance Associated With the Adoption of Resistance Phenotypes

Bacteria can sense the proximity of a surface, up-regulate production of EPS and rapidly alter their biocide susceptibility after binding. In some instances, 3–5 fold decreases in susceptibility occurred immediately on attachment in the presence of biocides that exceeded the minimum inhibitory concentration for planktonic cells (Fux et al., 2005). The magnitude of the decreases in susceptibility observed immediately after bacterial attachment, but before biofilm formation, is generally far less than that observed in mature biofilms and is insufficient to account for the reported levels of resistance in biofilm communities (Gilbert et al., 2002).

The microorganisms generate physiological changes that act to protect the cell from various environmental stresses. Thus, the cells are protected from the detrimental effects of heat shock, cold shock, changes in pH and many biocides. Nevertheless, the physiological changes begin when cells attach to a surface, by expressing a biofilm phenotype that can confer resistance face to environmental stress (Mah and O'Toole, 2001; Stewart et al., 2015). This resistant phenotype might be induced by nutrient limitation, certain types of stresses, high cell density, efflux of the treatment agent or a combination of these phenomena.

The role of quorum sensing in biocide is not yet clear. It has been suggested that regulation of EPS, under the control of signal molecules such as *N*-acyl homoserine lactones is responsible for the early transcriptional events associated with biofilm formation (Davies et al., 1998). Such global regulators are responsive to increase cell density beyond critical threshold values, and may be general regulators of biofilm-specific physiology (Davies et al., 1998). In biofilms, signal molecules would become concentrated within geometric centre of biofilm, thereby increasing EPS production. This would alter the distribution and density of cells throughout the matrix and confer some level of structural organization upon the community to provide customized microniches at various points within the biofilm (Gilbert et al., 2002). Brooun et al. (2000) showed that *P. aeruginosa* mutants defective in quorum sensing were unaffected in their resistance to biocides and antibiotics. Nevertheless, Mah and O'Toole (2001) suggested that additional experiments are required to elucidate the role of quorum sensing in antimicrobial resistance.

Sublethal concentrations of biocides might act as inducers/transcriptional activators of more tolerant phenotypes, such as those expressing the multidrug resistance operons and efflux pumps in *Escherichia coli* (Ma et al., 1993; Maira-Litran et al., 2000).

A novel hypothesis for the considerable recalcitrance of biofilm relates to the potential of damaged bacterial cells to undergo apoptosis or programmed cell death. Lewis (2000, 2001, 2010, 2017) suggested that death of cells following treatment with biocides results not from direct action of the agent but from a programmed suicide mechanism and cellular lysis. Following the absence of an adverse condition, the damaged persistent cells would grow rapidly in the presence of nutrients released from their lysed community partners and the community would become restored. These cells would survive treatment phases and proliferate in the post-treatment phase, thereby stimulating considerable recalcitrance upon the biofilm community. More recently, persister cells of *P. fluorescens* were found in biofilms exposed to *ortho*-phthalaldehyde, a biocide used for high-level disinfection (Simões et al., 2011).

In addition to the recognized resistance of biofilms there is a conspicuous absence of novel and effective control strategies. In the future, the use of novel biocides will even become more critical especially in Europe as a result of the Biocidal Product Directive (BPD) (Wypych and Wypych, 2015). The most recent Regulation (EU) No 528/2012 of the European Parliament and the Council (2012), concerning the making available on the market and use of biocidal products, outlines the important aspects of the use of biocidal products and governs principles of introduction of new product to the market. The BPD will have two major consequences:

- (1) Decrease in number of biocidal actives available to customers. There are estimations that this number will decrease in Europe from 1500 to 2000 actives today to less than 300–500 actives in the future (Wypych and Wypych, 2015).
- (2) Decline in new product introductions, because initial cost will be much higher and the return on investment will take longer.

There will be also an increasing pressure to substitute biocides which give rise to concerns regarding their toxicological or ecotoxicological properties. In parallel, microorganisms will continue acquiring resistance to antimicrobial agents, including to biocides. For example, Simões et al. (2006) found that a *Pseudomonas* strain exposed for 30 min to the quaternary ammonium compound cetyltrimethylammonium bromide expressed the OprM protein responsible for multiple drug resistance. Therefore, new information on the action and resistance of current biocides will enable their prudent use for effective disinfection.

A strategy of potential interest to replenish the biocide pipeline is the off-label use of chemical molecules currently applied in industrial products and process. Phytochemicals, currently used as food additives and food preservatives, are an under-exploited source of antimicrobial products (Cowan, 1999; Simões et al., 2009). Pine oil is probably the only plant-derived product already used in disinfection (Dellano et al., 2009). Details of structures and sources of many antimicrobial phytochemicals have been widely compiled, and evidence of the functions of these products has also been reviewed (Simões et al., 2009; Borges et al., 2016). It is clear that phytochemical products may inhibit bacterial growth by different mechanisms than the presently used biocides (Gomes et al., 2016; Malheiro et al., 2016; Simões et al., 2009). In fact, there is an encouragement to replace the toxic biocides for more readily antimicrobial agents, like naturally-produced compounds, such as plant extracts that will be more easily biodegraded and, consequently, environmentally acceptable (Guimet and De Saravia, 2005).

Phytochemical Compositions Used as Disinfectants

Plants synthesize a vast range of organic compounds that are traditionally classified as primary and secondary metabolites. Primary metabolites are compounds that have essential roles associated with photosynthesis, respiration, and growth and development. These include sugars, fatty acids, amino acids and nucleic acids (Kliebenstein and Osbourn, 2012; Theis and Lerda, 2003). Secondary metabolites, also referred to as natural products or phytochemicals, are considered to be those chemicals required for plant interactions with the environment, as pest and pathogen defense compounds, attractants for pollinators and seed-dispersing animals, allelopathic agents and ultraviolet-B sunscreens. These are structurally diverse and many are distributed among a very limited number of species within the plant kingdom, many of which accumulate in surprisingly high concentrations in some species (Bourgaud et al., 2001; Kliebenstein and Osbourn, 2012).

The natural products derived from medical plants have proven to be an abundant source of biologically active compounds, many of which might indeed be potential source of new antimicrobial agents. Plant products have been used since ancient time for flavoring foods and beverages, and also for medicinal purposes with varying success to cure and prevent diseases. As there are approximately 250,000–500,000 plant species occurring worldwide, of which a small percentage has been phytochemically explored till date, there is great potential for discovering new bioactive compounds (Borris, 1996; Negi, 2012; Palombo, 2011). Plants are potential sources of natural bioactive compounds such as secondary metabolites and antioxidants. They adsorb the sun light and produce high levels of oxygen and secondary metabolites by photosynthesis (Ghasemzadeh and Ghasemzadeh, 2011). The antimicrobial activity found in plant extracts has been attributed to some of the secondary metabolites, normally referred to as phytochemicals, which are biosynthesized to protect the plant against microbial infections and other external stress conditions (Malheiro et al., 2016).

The proven effectiveness of several phytochemicals, generally with low cytotoxicity, environmentally friendly, degradable and affordable, against microorganisms makes them a rich source of antimicrobial agents and, consequently, an interestingly alternative to commonly used benchmark biocides (Upadhyay et al., 2014). Additionally, an important benefit of using plant-derived antimicrobials is that they do not exhibit the side effects often associated with the use of synthetic chemicals (Upadhyay et al., 2014). The structural diversity of plant-derived compounds is immense and, the impact of antimicrobial action they produce against microorganisms depends on their structural configuration. Secondary metabolites can be classified based on their chemical structure, which also influences their antimicrobial properties, and the major groups that are responsible for antimicrobial activity from plants include phenolics, terpenoids and alkaloids (Fig. 1) (Gyawali and Ibrahim, 2014).

Classification of Phenolic Compounds

Phenolic compounds are the largest category of phytochemicals and the most widely distributed in the plant kingdom. These compounds are important determinants in the sensory and nutritional quality of fruits, vegetables and other plants (Balasundram et al., 2006; Saxena et al., 2013). Phenolic compounds possess an aromatic ring, bearing one or more hydroxyl groups, and their structures may range from that of a simple phenolic molecule to that of a complex high-molecular mass polymer (Balasundram

Fig. 1 Scheme presenting the major groups of plants phytochemicals. Based on Saxena, M., Saxena, J., Nema, R., Singh, D., and Gupta, A., 2013. Phytochemistry of medicinal plants. *Journal of Pharmacognosy and Phytochemistry* 1, 168–182.

et al., 2006). These compounds may be classified into different groups according to the number of phenol rings that they contain and to the structural elements that bind these rings to one another. The main groups of these compounds are flavonoids, phenolic acids, and tannins (D'Archivio et al., 2007; King and Young, 1999).

Flavonoids

Flavonoids are pigmented compounds found in fruits and flowers, being present in high concentrations in the epidermis of leaves and the skin of fruits. The basic structural feature of flavonoid compounds is the 2-phenyl-benzo[α]pyrane or flavane nucleus, which consists of two benzene rings linked through a heterocyclic pyrane ring (Ahmad et al., 2015; Cowan, 1999; Cushnie and Lamb, 2005; Savoia, 2012). These compounds may be divided in subclasses as a function of the type of heterocycle involved: flavones, flavonols, flavan-3-ols, isoflavones, flavanones, and anthocyanidins, of which flavones and flavonols are the most widely occurring and structurally diverse (Ignat et al., 2011; Manach et al., 2004). The source of variance in flavonoids includes: differences in the ring structure of the aglycone and in its state of oxidation or reduction; differences in the extent of hydroxylation of the aglycone and in the positions of the hydroxyl groups; and difference in the derivatization of the hydroxyl groups, e.g., with methyl groups, carbohydrates, or isoprenoids (Ahmad et al., 2015; Havsteen, 2002).

A marked antimicrobial property of flavonoids against a variety of bacterial pathogens has been observed (Cazarolli et al., 2008; Cushnie and Lamb, 2005; Wächter et al., 1999). Mechanism of action of flavonoids against bacteria may be attributable to up to three different ways, which include damage of cytoplasmic membrane by perforation mechanism and decrease in membrane fluidity, inhibitory effect on energy metabolism and inhibition of synthesis of nucleic acids (Ahmad et al., 2015; Cushnie and Lamb, 2011). Work with compounds in the flavonol and flavan-3-ol classes suggests that they damage the cytoplasmic membrane. Work with flavan-3-ols and isoflavones suggests that they inhibit nucleic acid synthesis. In addition, compounds in the flavonol, flavan-3-ol and flavone classes have shown to inhibit energy metabolism (Ahmad et al., 2015; Cushnie and Lamb, 2011). Evidences about another two mechanisms of flavonoid action have also been presented, which are the inhibition of cell wall synthesis and inhibition of cell membrane synthesis (Ahmad et al., 2015; Cushnie and Lamb, 2011).

Phenolic acids

Phenolic acid compounds form a diverse group that includes the widely distributed hydroxybenzoic and hydroxycinnamic acids. These derivatives differ in the patterns of the hydroxylations and methoxylations of their aromatic rings. Although the basic skeleton remains the same, the numbers and positions of the hydroxyl groups on the aromatic ring, and the type of substituents, cause significant changes on the properties of the phenolic products (Robbins, 2003; Sroka and Cisowski, 2003; Stalikas, 2007).

The site(s) and number of hydroxyl groups on the phenol group are thought to be related to their relative toxicity to microorganisms, with evidence that increased hydroxylation results in increased toxicity. The mechanism thought to be responsible for the toxicity of phenols and phenolic acids to microorganisms include enzyme inhibition by the oxidized compounds, possible through reaction with sulfhydryl groups or through more non-specific interactions with the proteins (Cowan, 1999; Samy and Gopalakrishnakone, 2010; Saavedra et al., 2010). Phenols can also inhibit the synthesis of nucleic acids of both Gram-negative and Gram-positive bacteria (Saavedra et al., 2010).

Hydroxycinnamic acids occur frequently in foods as simple esters with quinic acid or glucose, while hydroxybenzoic acid derivatives are mainly present in foods in the form of glucosides. Glucose esters have found only occasionally (Ignat et al., 2011; Mattila and Hellstrom, 2007; Mattila et al., 2006). Hydroxybenzoic acids include gallic, p-hydroxybenzoic, protocatechuic, vanillic and syringic acids. Hydroxycinnamic acids, on the other hand, are aromatic compounds with a three-carbon side chain, and caffeic, ferulic, p-coumaric and sinapic acids are the most common representatives occasionally (Ignat et al., 2011; Manach et al., 2004; Mattila et al., 2006).

Phenolic acids are commonly used as preservatives in food applications, due to their antioxidant and antimicrobial properties (Robbins, 2003). However, diverse phenolic acids are promising candidates for cleaning and disinfection due also to their antimicrobial properties and low cutaneous toxicity (Borges et al., 2012; Lemos et al., 2014; Lou et al., 2012; Phan et al., 2001).

Tannins

Tannins are water-soluble polyphenols that are commonly found in almost every plant part, like bark, wood, leaves, fruits, and roots. The properties of tannins are based on their chemical structures having two or three phenolic hydroxyl groups on a phenol ring, in a molecule of moderate large size. They can be classified into two groups: hydrolyzable and non-hydrolyzable (condensed tannins). Hydrolysable tannins are based on gallic acid, usually as multiple esters with D-glucose, while the more numerous condensed tannins (often called proanthocyanidins) are derived from flavonoid monomers. Tannic acid is an important gallotanin belonging to the hydrolysable class, while catechin belongs to the non-hydrolysable class (Akiyama et al., 2001; Barbehenn and Constabel, 2011; Cowan, 1999; Okuda and Ito, 2011).

The mode of antimicrobial action of tannins appear to be related to the inhibition of extracellular microbial enzymes, deprivation of the substrates required for microbial growth or direct action on microbial metabolism through inhibition of oxidative phosphorylation. Many microbial enzymes, such as cellulase, pectinase, xylanase, peroxidase, laccase, and glycosyl transferase were inhibited when mixed with tannins. The antimicrobial activity of tannins may also be related to their action on the microbial membranes. Complexation of metal ions by tannins could be another possible mechanism. Tannins are capable of chelating many metal ions, thus reducing the availability of essential metal ions for microorganisms (Akiyama et al., 2001; Chung et al., 1998a,b; Scalbert, 1991).

Terpenoids and Essential Oils

Essential oils (EOs) are a complex mixture of natural, volatile, and aromatic compounds obtained from plant material (flowers, buds, seeds, leaves, twigs, bark, herbs, wood, fruit and roots). EOs are secondary metabolites that are highly enriched in compounds based on an isoprene structure (Bakkali et al., 2008; Barbieri et al., 2017; Cowan, 1999; Nerio et al., 2010). These plant secondary metabolites have their greatest use in food as flavourings, in perfumes as fragrances, in aftershaves and in pharmaceuticals for their functional properties. Moreover, it has been recognized that some EOs have antimicrobial properties (Burt, 2004; Dorman and Deans, 2000; Hammer et al., 1999; Rota et al., 2004).

An important characteristic of EOs and their components is their hydrophobicity, which enables them to partition in the lipids of the bacterial cell membrane and mitochondria, disturbing the structures and rendering them more permeable. Therefore, the mode of action of EOs is based on their ability to disrupt cell wall and cytoplasmic membrane, leading to lysis and leakage of intracellular compounds (Bakkali et al., 2008; Ben Arfa et al., 2006; Burt, 2004; Liolios et al., 2009). In this context, oregano essential oil was reported to induce permeability alteration in *Staphylococcus aureus* and *P. aeruginosa* membranes with a consequent leakage of intracellular content (Lambert et al., 2001). Nevertheless, it has been proposed that the chemical structure, such as the presence of the functional hydroxyl group and the aromaticity are also responsible for the antibacterial effect. Generally, phenolic compounds, having the hydroxyl group attached to a phenyl ring, have the greatest activity among the phytochemicals found in EOs (Dorman and Deans, 2000; Lambert et al., 2001).

The active compounds of EOs can be divided into four groups according to their chemical structure: terpenes, terpenoids, phenylpropenes, and "others" (Hyldgaard et al., 2012). Terpenes are hydrocarbons produced from the combination of several isoprene units. Terpenes contain a hydrocarbon backbone which can be rearranged into cyclic structures by cyclases, thus forming monocyclic or bicyclic structures (Hyldgaard et al., 2012; Nazzaro et al., 2013). The main terpenes are the monoterpenes and sesquiterpenes, but hemiterpenes, diterpenes, triterpenes and tetraterpenes also exist in EOs at low concentration. Monoterpenes consist of two isoprene units, being the most representative molecules constituting 90% of EOs extracted from many plants (Bakkali et al., 2008; Hyldgaard et al., 2012; Nazzaro et al., 2013; Tongnuanchan and Benjakul, 2014). Among the terpenes, p-cymene, limonene, terpinene, sabinene, and pinene are the most well-known (Hyldgaard et al., 2012; Nazzaro et al., 2013). Most terpenes do not have high inherent antimicrobial activity (Hyldgaard et al., 2012; Nazzaro et al., 2013).

Terpenoids are terpenes with added oxygen molecules or that have had their methyl groups moved or removed by specific enzymes. Terpenoids are derived from five-carbon isoprene units; most of terpenoids have multi cyclic structures that differ from one another in their functional groups and basic carbon skeletons (Barbieri et al., 2017; Hyldgaard et al., 2012; Nazzaro et al., 2013). Carvacrol, thymol, linalool, menthol, geraniol, linalyl acetate, citronellal, and piperitone are the most common and well-known terpenoids (Hyldgaard et al., 2012; Nazzaro et al., 2013). Terpenoids are active against a broad spectrum of microorganisms, with the most active monoterpenoids identified so far being carvacrol and thymol (Dorman and Deans, 2000; Hyldgaard et al., 2012). Carvacrol is a phenolic monoterpene that is found primarily in the essential oil from oregano, being one of the most investigated EO constituents showing antimicrobial activity against a broad-spectrum of bacteria (Aligiannis et al., 2001; Dorman and Deans, 2000; Knowles et al., 2005; Ultee et al., 2000). Carvacrol acts on microbial cells and causes structural and functional damage to their membranes with consequent loss of integrity and leakage of cellular material such as ions, ATP and nucleic acid (Hyldgaard et al., 2012; Nostro et al., 2007; Sikkema et al., 1995). Additionally, carvacrol is a volatile molecule that evaporates easily and its vapor phase has shown antimicrobial activity (Ben Arfa et al., 2006; López et al., 2007; Skandamis and Nychas, 2002), which suggests interesting applicative prospects. The efficacy of carvacrol vapor was demonstrated against food-borne *E. coli* O157:H7 and *Salmonella* on the surface of freshly produced vegetables, such as lettuce, spinach and tomatoes (Obaidat and Frank, 2009a,

b). Thymol presents a structure similar to carvacrol, and it is a phenolic monoterpene that is found in the essential oil of thyme, being also one of the most explored EO constituents. Similarly to carvacrol, thymol antimicrobial activity results in structural and functional alterations in the cytoplasmic membrane that can damage the outer and inner membranes, and the interaction of thymol with the membrane affects its permeability resulting in the release of ions and ATP (Hyldgaard et al., 2012; Nostro et al., 2007; Sikkema et al., 1995). The high antimicrobial activity of terpenoids compared to terpenes can be attributed to the functional moieties, since the chemical structure of terpenoids are closely related to that of terpenes (Hyldgaard et al., 2012).

Phenylpropenes are named as such because they contain a six-carbon aromatic phenol group and a three-carbon propene tail from cinnamic acid, which is produced in the first step of phenylpropanoid biosynthesis. These compounds constitute a relatively small part of EOs, and those that have been most thoroughly studied are eugenol, isoeugenol, vanillin, safrole, and cinnamaldehyde (Hyldgaard et al., 2012; Nazzaro et al., 2013). Eugenol, a phenylpropene present in many plants, is the main component of clove essential oil and its antimicrobial activity is related to the ability to permeabilize the cell membrane and interact with proteins. The action of eugenol on membranes occurs mainly by a non-specific permeabilization, which has been showed in various studies as increased transport of potassium and ATP out of the cells (Devi et al., 2010; Gill and Holley, 2006; Hyldgaard et al., 2012). Moreover, the hydroxyl group present in eugenol is believed to bind and affect the properties of proteins, thereby contributing to eugenol inhibitory effect at sub-lethal concentrations (Devi et al., 2010; Hyldgaard et al., 2012). Eugenol has been showing excellent antimicrobial activity against a wide range of bacteria, including *E. coli*, *S. aureus*, and *P. aeruginosa* (Gill and Holley, 2006; Walsh et al., 2003). On the other hand, the antimicrobial mode of action of cinnamaldehyde, another phenylpropene, is not clear. There are three things that are thought to occur: at low concentrations it inhibits different enzymes involved in cytokinesis; at higher but sub-lethal concentrations it acts as an ATPase inhibitor; and at lethal concentrations it perturbs the cell membrane (Hyldgaard et al., 2012). Cinnamaldehyde has also been reported to have an antimicrobial effect against a broad range of microorganisms (Sanla-Ead et al., 2012; Shen et al., 2015; Ye et al., 2013).

Alkaloids

Alkaloids are produced by a large variety of organisms such as plants, bacteria, fungi and animals and have been used in medicine since ancient times. Alkaloids can occur in any part of the plant, though specific compounds may be limited to a certain part (Barbieri et al., 2017; Cushnie et al., 2014). Alkaloids are characterized by great structural diversity, the presence of a basic nitrogen atom being the only unifying feature. Most alkaloids possess just one nitrogen atom, but some have up to five (Cushnie et al., 2014). No single taxonomic principle exists that would allow consistent classification of all alkaloids, being normally classified according to chemical structure, biochemical origin and/or natural origin. In terms of chemical structure, there are two wide divisions of alkaloids: the heterocyclic alkaloids, also known as typical alkaloids, which contain nitrogen in the heterocycle; and the non-heterocyclic alkaloids, also known as atypical alkaloids or protoalkaloids, which contain nitrogen in a side chain (Amirkia and Heinrich, 2014; Cushnie et al., 2014).

Numerous plant families are known to produce alkaloids and it has been reported that several of them possess high antimicrobial activity, including against *E. coli*, *P. aeruginosa*, *Proteus mirabilis*, *S. aureus*, *Bacillus subtilis*, *Raoultella planticola*, *Enterobacter aerogens*, *Agrobacterium tumefaciens*, and *Klebsiella pneumonia* (Saleem et al., 2010; Singh and Kumar, 2012). The mechanism of action of aromatic planar quaternary alkaloids such as berberine and harmane is attributed to their ability to intercalate with DNA thereby resulting in impaired cell division and cell death (Cowan, 1999; Savoia, 2012).

Conclusions

The extensive use of biocides for microbial growth control has considerable environmental and economic impacts. The misuse of more aggressive biocides and increased doses (as a way to overcome the resistance phenomena) constitutes an extra risk to public health. These measures can lead to the selection of pathogens insusceptible to the main available antimicrobials. Antimicrobial resistance is even more significant when cells are embedded in a biofilm. This has encouraged the replacement of toxic biocides with more readily antimicrobial agents, like natural-produced compounds. In this context, plants are potential sources of natural bioactive molecules. Phytochemicals have already shown great effectiveness against a broad spectrum of microorganisms making them a rich source of biocides and, consequently, an interestingly alternative to commonly used benchmark biocides.

Glossary

Alteration Change in materials that does not necessarily involve a worsening in their conservative characteristics.

Biodeterioration Every form of irreversible alteration that causes changes/modifications in the properties of the materials due to metabolic activity and the development of one or more microbial population.

Biodeterioration (general) A process in the environment that recycles complex organic matter (and materials), and is an integral component of the life cycle.

Bioreceptivity Tendency of a material to be colonized by one or more organisms not always linked to a biodeterioration process.

Cultural heritage Term now utilized to cover the immensely diverse mass of documents and other historical objects of all types upon which societies confer a particular artistic, historic, or ethnologic value.

Decay Change in materials that always involves a worsening in their conservative characteristics.

Efflorescence Presence of a deposit of inorganic substances on stone or masonry surfaces that is not originally there in the sound material.

Foxing Deterioration of paper occurring as brownish, reddish stains because of the activity of microorganisms (majority) or the oxidation and/or formation of heavy metals deposits.

Patina Originally defined by Filippo Baldinucci (*Dictionary of Art*, 1681) as the time-dependent darkening of frescos and oil painting. Today, the term denotes the sum of all changes that the surface layers of objects of art are submitted to and inherit from environmental, biological, and substrate-related factors; in a broad sense, a term denoting all.

Abbreviations

DGGE Denaturing gradient gel electrophoresis

EPS Extracellular polymeric substances

MCF Microcolonial fungi

MIC Microbially influenced corrosion

SRB Sulfate-reducing bacteria

Defining Statement

This article gives an overview of the biodeterioration of cultural heritage caused by biodeteriogen agents and their mechanisms and processes. Basic information on the material composition of objects of art is provided to address the problem of biodeterioration. Finally, it stresses and highlights the relevance of preservation and conservation practices.

Biodeterioration

Biodeterioration is a phenomenon that affects all materials, including those used in buildings, metals, monuments, pigments, frescoes, and so on. Stone deterioration is a natural process resulting from exposure to atmospheric agents and is referred to as stone/rock disintegration, with debris (gravel, sand, and clay) that, through transportation and sedimentation processes, can then constitute new rock, being formed.

[☆]*Change History*: August 2017. T. Lech updated section Biodeterioration, made small edits in sections Biodeteriogens and small edits in section Organic Material/Parchment, added subsection Textile in the section Organic Material, made small updates in section Methods of Control and Prevention, added sections Molecular Methods in Microbial Hazard Identification, and Protection of Cultural Heritage Collections, added new figs. 5–8, updated section Further Reading.

This article is an update of G. Ranalli, E. Zanardini, C. Sorlini, Biodeterioration – Including Cultural Heritage, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 191–205.

Table 1 Activities of main microbial deteriogens capable to use organic and inorganic substrates related to several matrices of cultural heritage

<i>Microbial deteriogens</i>	<i>Activities</i>	<i>Substrates</i>	<i>Matrices</i>	<i>Genera</i>
Proteolytic bacteria (ammonifying)	Hydrolyze, peptidase	Casein, egg yolk, collagen	Parchment, leather, wool, silk, frescoes	<i>Pseudomonas</i> , <i>Sarcina</i> , <i>Bacteroides</i>
Cellulolytic bacteria	Cellulase	Cellulose, tannins, resins, shellac, waxes, etc.	Textile fibers, (cotton, linen, jute, hemp), paper	<i>Cytophaga</i> , <i>Sporocytophaga</i> , <i>Sorangium</i> , <i>Vibrio</i> , <i>Cellvibrio</i> , <i>Cellfalcicula</i>
Amylolytic	Amylase	Starch	Frescoes	<i>Bacillus</i> , <i>Clostridium</i>
Lipolytic bacteria	Lipase	Fats, walnut and linseed oils, waxes	Wood, frescoes	<i>Bacillus</i> , <i>Alcaligenes</i> , <i>Staphylococcus</i> , <i>Clostridium</i>
Nitrifying bacteria	Corrosion by NO_2^- and NO_3^- yield	NH_3	Stone and metal artworks, varnish	<i>Nitrosomonas</i> , <i>Nitrobacter</i>
Denitrifying bacteria	Denitrification (anaerobiosis)	Several organic substrates	Stone artworks	<i>Pseudomonas</i> , <i>Bacillus</i> , <i>Vibrio</i>
Sulfate-oxidizing bacteria	Oxidations	S compounds	Stone artworks	<i>Thiobacillus</i> , <i>Thiosphaera</i>
Sulfate-reducing bacteria	Corrosion by H_2S (anaerobiosis)	S compounds	Stone and metal artworks	<i>Desulfovibrio</i> , <i>Desulfobacter</i> , <i>Desulfococcus</i>
Heterotrophic bacteria	Red/ox; weak corrosion	Inorganic compounds (air pollutants); cell lyses of organotrophs	Several materials	<i>Idrogenomonas</i> , <i>Thiobacillus</i>
Actinomycetes	Hydrolytic; Mechanical action	Cellulose, hemicellulose, etc.	Textile fibers (cotton, linen, jute, hemp)	<i>Streptomyces</i> , <i>Nocardia</i> , <i>Cellulomonas</i>
Yeasts	Fermentative	Carbohydrates	Frescoes, textile fibers	<i>Candida</i> , <i>Lypomyces</i> , <i>Cryptococcus</i> , <i>Torulopsis</i>
Fungi	Several (hydrolyze, proteinase, lipase); Mechanical action by hyphae penetration	Starch, cellulose, hemicellulose, lignin	Wood and stone artworks, frescoes, mortar, plaster, varnish, paper	<i>Geotrichum</i> , <i>Pullularia</i> , <i>Cladosporium</i> , <i>Tricoderma</i> , <i>Aspergillus</i> , <i>Alternaria</i> , <i>Penicillium</i>
Algae	Photosynthetic	Inorganic compounds	Stone artworks, frescoes, mortar, varnish, metals	<i>Chlorococcales</i> order <i>Scenedesmus</i> , <i>Chlorella</i>

Outdoor artwork in particular suffers deterioration processes, especially in urban and industrialized areas where atmospheric pollutants and climatic conditions act together. Indeed, rain and pollution act directly on stone surfaces, altering their chemical composition, while wind and thermal differences tend to lead to an increase in specific types of stone surfaces, resulting in the formation of microfissures and microfractures. This can give rise to opportune conditions for the development and growth of microbes. Biodeterioration is defined as any form of irreversible alteration, implying a modification in the properties of materials due to metabolic activity and the growth of organisms called biodeteriogens. Atmospheric pollutants play a determining role in deterioration processes, and industrial development over the past century has led to an increase in the number of pollutants and caused accelerated deterioration in artwork exposed to the open air. Apart from corrosive substances present as atmospheric contaminants, other compounds can also accumulate on surfaces and favor the colonization of specific microbial populations able to utilize such compounds for growth (Table 1).

Deterioration is a phenomenon that occurs in materials of every type, including those used in buildings, metals, stones of monuments, fresco pigments, and so on. The deterioration of stone on the geological temporal scale is part of a natural cycle that leads to the disintegration of rock exposed to atmospheric agents, forming detritus material (gravel, sand, and clay) that, through processes of transportation, sedimentation, and diagenesis, can constitute new rock. Artwork out in the open air in highly industrialized areas is especially subjected to deterioration as there is direct interaction with atmospheric polluting agents as well as climatic conditions. Rain and pollutants act directly on the stone surfaces, altering the chemical composition of the material. Wind, extreme temperatures, and aggressive pollutants present in the atmosphere provoke over time a deterioration that leads to an increase in the specific surfaces of marble, with the phenomenon of decohesion and the formation of microfissures. After the surface has deteriorated, conditions become favorable for microbial attack and the development of living organisms (Fig. 1).

Biological agents such as bacteria, algae, fungi, lichens, mosses, and plants can colonize different substrates (paper, wood, stone, frescoes, paintings, etc.) and damage both surfaces and deep layers. Indeed, microflora able to grow on objects of art have a very complex ecosystem, and their development varies depending on the environmental conditions and the chemico-physical properties of the substrate. Also, climatic conditions play an important role. Actinomycetes and mycetes growing on a stone surface produce acids and substances, and these react with the substrate, causing its disintegration and allowing penetration of the hyphae into internal layers. Thus, such processes represent both chemical and mechanical deterioration. Furthermore, organisms often aggregate and produce biofilm and biological patina.

Fig. 1 Ecological succession on the artwork by autotrophic-heterotrophic microorganisms. Photo: G. Ranalli, G. Lustrato.

Biodeterioration is a complex process, usually involving simultaneous activity of various microorganisms. Microbial consortia may be less or more complex and their development frequently depends upon the appearance of microorganisms with low requirements, the presence and metabolic activity of which enable formation of a specific microclimate (frequently provision of higher relative humidity on the material surface or delivering nutrients), thereby allowing settlement of subsequent more demanding microorganisms. As has been mentioned above, the ability of forming microbial consortia is completely different in external environments (surfaces of containers, building outer walls, etc.) than in enclosed rooms where historical objects are stored. This mainly depends on the source of carbon in the environment and potential growth of autotrophic microorganisms.

As shown in recent research, biofilm formation is a multi-step process. The first stage is reversible attachment, with the greatest impact of gravitational forces between organisms and material, including the properties of the material (e.g., hydrophilic or hydrophobic area), as well as Van der Waals and Debye forces. This stage is followed by irreversible attachment which involves chemical forces and development of extracellular polymeric substance (EPS). EPS is a mix of polysaccharides, proteins, nucleic acids, lipids and other substances secreted by microorganisms, and its composition depends on the diversity of microorganisms creating the consortium. On the one hand, EPS facilitates more permanent attachment between microorganisms and the surface and stabilizes the biofilm on the surface. On the other, it ensures protection from unfavorable effects of environmental factors. Moreover, EPS is responsible for retention and accumulation of organic and non-organic substances essential for the biofilm to develop. The subsequent stage of biofilm formation is its maturation which involves development of a heterogeneous structure of cells connected with one another by channels used for transportation of nutrients and other metabolites. In a structure organized in such a way, microbial diversity is considerable, and owing to reciprocal interactions and an ability to produce a wider range of lytic enzymes, they gain greater biodeteriorative potential in both organic and non-organic materials. The final stage of biofilm

formation is its dispersion. Of note is the fact that the formation of a classical biofilm structure requires favoring environmental conditions and usually appears at the interface of phases.

The phenomenology of the microbial attack and the type of alteration depend on both the environmental conditions and the characteristics and state of the stone surface. Indeed, biodeterioration is a secondary deterioration process that occurs in substrates that have already been altered by chemical and physical damages.

Abiotic Factors

The main abiotic factors that affect the growth of biodeteriogens are humidity, temperature and their fluctuations, light (UV radiation), the type of substrate, ventilation, and air pollution. Humidity strongly favors the growth of algae and fungi. Light, both natural and artificial, is necessary for photosynthetic microorganisms (algae and cyanobacteria), lichens, mosses, and plants. Temperatures higher than 30°C together with high relative humidity accelerate all biological processes, while low temperatures (4°C) delay them. The substrate composition of artwork plays an important role in the growth of organisms. A material that is mainly composed of organic substances favors the growth of heterotrophs, particularly mycetes, while materials consisting mainly of inorganic substances, such as stone, favor the growth of chemolithotrophs and phototrophs. Also, the properties of materials, such as mineralogical composition, porosity, structural characteristics, along with the conservation state, can affect microbial colonization. This tendency, defined as the bioreceptivity of a surface, includes all the properties and characteristics of a material that contribute to, and favor, microbial growth. Ventilation is very important in the colonization process in order to reduce humidity, prevent condensate formation on the surface, avoid stagnancy of polluted air, and prevent atmospheric particulate and microorganism deposition on surfaces. The organic chemical pollutants in the atmosphere serve as an important carbon source for organisms. There is a strong correlation between aerobiology and biodeterioration. In fact, air represents the most important medium for the transportation of microorganisms (vegetative cells and spores) that can reach the surface of artistic manufactures and give rise to colonization. Other factors that can affect this process are the type of microorganism, the chemical composition of the substrate, and climatic conditions.

Mechanisms of Biodeterioration

Deterioration is the term used to define the modification of a material that results in a worsening in the material's characteristics from the point of view of conservation. Instead, the term 'alteration' indicates a modification of a material, but it does not necessarily imply a worsening in its characteristics from the conservation point of view. Indeed, the aggression of living organisms on materials can occur in two different ways that, however, act in synergy toward the disintegration of the material.

Chemical aggression

Chemical aggression occurs through the decomposition of a substrate and its transformation due to the direct action of intermediate and final products of microbial metabolism. Such deterioration, exclusive to stonework, is defined as biocorrosion. The metabolites mainly involved in this deterioration mechanism are organic and inorganic acids and chelating substances. The acids produced by the organisms react with the material of the stone, generally the insoluble salts, dissolving them and exposing them to be washed away by rainwater. All living aerobic organisms produce, through respiration, CO₂ as a final metabolism product, and when this reacts with water on limestone material, it is transformed to carbonic acid (H₂CO₃). Although weak, this acid still dissolves the relatively insoluble calcium and magnesium carbonates to form their bicarbonates that are very soluble and easily removed by heavy rain. The sulfuric acid produced biologically by the sulfur-oxidizing bacteria, particularly the *Thiobacillus* genera, and the nitric acid produced from the nitrifying *Nitrobacter* and *Nitrosomonas* bacteria act as powerful corrosives, reacting with calcium ions to form the soluble and easily washed away calcium sulfate (chalk) and calcium nitrate. All acidic substances taking part in chemical attack processes act through an acidolysis mechanism. The chelating substances, some of which are organic acids, dissolve the trivalent metallic cations of the stone, and thus provoke its disintegration. On materials containing organic substances (frescoes, tapestries, and paintings), there are biochemical processes due to the activity of exoenzymes from heterotrophic colonizers, mostly fungi, that use the organic substances present (casein, solvents, organic acids, and pigments of natural origin) as growth substrates. Indeed, bacteria developing on wall paintings can provoke variations in the color of paintings not only through pigment production but also through the excretion of metabolic products that provoke a loss of color in parts of the painting on the wall.

Aggression via mechanics

Stones exposed to the open air suffer accelerated deterioration of a mechanical type – washing by the rain, thermal excursions in the form of freezing and thawing cycles, and the action of the wind. Mechanical aggression by living organisms occurs through the growth of microorganisms or parts thereof (hyphae of fungi, rizine of licheni, and superior plant roots). Such action is manifested in the form of fissures and fractures of the attacked substrate, but there is no variation in the chemical composition of the material. This mechanical aggression becomes much more important when the colonizing organisms are

not limited to the development on the surface of the material (epiphytic organisms) but actively penetrate the stone (endolytic organisms), provoking disintegration of the material. Toward the end, there is a physical/mechanical attack by the filamentous microorganisms that taking advantage of the material's porosity penetrate and cause its disintegration. Some microorganisms cause damage due to variation in the water mass volume in the tissues; as such tissues are subject to dehydration and rehydration. A particular type of degradation, associated indirectly with biodeterioration, can be seen in restoration interventions. Indeed, damage is often due to operators who are not fully aware of the many pitfalls of dealing manually with plants anchored to walls or the cleaning of surfaces covered by biological patina.

Biodeteriogens

Biodeteriogens are organisms that participate in the biodeterioration process of materials, including historical and artistic manufacts. Such organisms are autotrophs and heterotrophs and colonize different types of inorganic (stonework, metals, and glass) and organic materials (paper, wood, parchment, leather, textile, etc.). Until the last decade, it was always considered that the first colonizers of stone were autotrophic organisms (both photoautotrophs and chemolithotrophs) able to utilize CO_2 as the carbon source, while the colonization by heterotrophs on the surface occurred only subsequently, with these organisms growing on the organic compounds released by the cellular lyses of autotrophs.

It was recently demonstrated that microbial symbiotic association can occur on stone surfaces. Under certain environmental conditions (i.e., in polluted areas), specific and adapted heterotrophic microflora have been evidenced in cometabolic processes associated with the degradation of organic atmospheric pollutants accumulated on exposed surfaces. In these cases, pollutants acting directly in the deterioration process and causing chemical damage on the superficial layers can also act indirectly as a nutritional source for microorganisms, favoring the selection of a specific heterotrophic microflora. Indeed, it has been demonstrated that some of these microorganisms growing on stonework exposed to air pollution are able to degrade aliphatic and aromatic hydrocarbons, including polycyclic compounds, as the carbon source for their growth. Furthermore, the metabolic potentiality of the colonizing microflora has been confirmed by the presence of functional genes that encode enzymes involved in the degradation of aromatic compounds, such as monooxygenases and dioxygenases. Thus, on the basis of this metabolic capability, heterotrophic microflora can also be considered the first colonizer of pollutant-exposed stonework. Note also that the microorganisms can grow using the very compounds applied to the stonework as a protective and consolidating agent (Fig. 2).

Finally, some microorganisms that grow on art objects can also exhibit particular metabolic conditions, lying dormant or in a noncultivable state under oligotrophic conditions for many years. The principal groups of microorganisms that are biodeteriogenic with regard to cultural properties are listed below. They are classified according to autotrophic or heterotrophic nutritional characteristics.

Bacteria (Eubacteria and Archaea)

Bacteria are unicellular microorganisms, principally characterized by the prokaryotic organization of their cells, that show a wide range of metabolic functions and capabilities. As per the phylogenetic tree of life, two prokaryotic domains, Bacteria and Archaea (unicellular organisms that have a nucleus but no membrane) are present. The main differences in the cellular structure of bacterial

Fig. 2 Scanning electron micrograph of biofilm on altered marble surface. Photo: G. Ranalli.

and archaeal microorganisms are seen in the composition of the cell wall: Peptidoglycan in most Eubacteria and pseudomurein, polysaccharides, proteins, or glycoproteins in the Archaea, while the RNA polymerase is made up of a greater number of subunits for the bacteria, between 8 and 12, as compared to the 4 found in Eubacteria. Given the different cell wall composition, the Eubacteria are subdivided into Gram-positive and Gram-negative. The groups most frequently associated with artwork deterioration are considered here.

Chemolithotrophic bacteria

Sulfur-oxidizing bacteria are often considered one of the most dangerous groups for the conservation of stonework (chemolithotrophic) as they produce sulfuric acid, an inorganic acid that has a strong degrading action through the oxidation of hydrogen sulfide, elemental sulfur, and thiosulfates. Indeed, the most dangerous for artifacts are the thiobacilli (*Thiobacillus* and *Thiomicrospira*) as they directly oxidize sulfides to sulfates and their ecological characteristics favor a greater production of sulfuric acid.

Nitrifying bacteria include ammonia-oxidizing bacteria (*Nitrosomonas* and *Nitrosococcus*) that oxidize ammonia to nitrous acid and nitrite-oxidizing bacteria that oxidize nitrous acid to nitric acid (*Nitrobacter* and *Nitrococcus*). The metabolic process is called nitrification. Nitrifying bacteria play an important role in stone weathering because of nitric acid production.

Hydrogen bacteria use molecular hydrogen as a source of energy, converting CO₂ to organic carbon. Their importance lies in the fact that they remain active under limited environmental conditions and even in the temporary absence of the primary energy source. Almost all are facultative chemolithotrophic organisms, having the capacity to use organic compounds as the energy source (chemoorganotrophs). Hydrogen bacteria are active in both the presence and the absence of organic substances, as long as the hydrogen concentration is high. Both Gram-positive (*Bacillus*) and Gram-negative organisms are found, the most common and well known being the *Pseudomonas*, *Paracoccus*, and *Alcaligenes*.

Ferrobacteria are microorganisms that obtain their energy from the aerobic oxidation of iron: from ferrous (Fe²⁺) to ferric (Fe³⁺). Ferrobacteria are found on stone containing pyrites (ferric sulfide), frescos and wall paintings, and so on, where reduced iron compounds were employed, and on iron artifacts. In acid environments, *Thiobacillus ferrooxidans* is the most frequently found, growing autotrophically by utilizing both ferrous ions and compounds reduced from sulfur as electron donors.

Heterotrophic bacteria

A great number of heterotrophic bacteria (Eubacteria and Archaea) are able to colonize artwork. Such bacteria are responsible for various types of enzymatic activity that can directly affect colonized materials, especially organic material. Heterotrophic bacteria have also been found frequently on inorganic materials such as stone monuments and mural paintings, and the great majority of them have been Gram-positive bacteria belonging to the genera *Bacillus*, *Brevibacillus*, *Micrococcus*, *Kocuria*, *Clostridium*, *Frankia*, *Geodermatophilus*, *Blastococcus*, *Staphylococcus*, *Streptomyces* and related genera (such as *Nocardia*, *Rhodococcus*, *Streptovorticillium*, and *Micromonospora*), and Gram-negative bacteria (*Pseudomonas* and *Acinetobacter*). Recently, halophilous Archaeal bacteria such as *Halomonas* and *Halococcus* were found on frescos. Heterotrophic bacteria can be distinguished according to the nature of their enzymatic activity:

Proteolytic and ammonifying bacteria

These bacteria hydrolyze proteinaceous substances to peptides and the peptides to amino acids, producing extracellular hydrolytic enzymes (i.e., protease and peptidase). The amino acids are then broken down with the liberation of ammonia. The most frequently identified species belong to the genera *Pseudomonas*, *Sarcina*, *Bacteroides*, and *Streptomyces*. Proteolytic bacteria are particularly dangerous for items of animal origin, such as parchment, leather, silk and wool.

Cellulolytic bacteria

These bacteria can be distinguished as primary cellulolytic bacteria and as facultative cellulolytic bacteria. The primary cellulolytic bacteria specialize in cellulose degradation, to such an extent that they are unable to grow if this compound is not present (*Cytophaga*, *Sperocytophaga*, and *Sporangium*), while the facultative cellulolytic bacteria are able to also utilize other organic compounds (*Vibrio*, *Cellvibrio*, and *Cellfalcicula*). Cellulolytic bacteria are quite common and have the capacity to break down lignin and other wood components such as resins, gums, dye, tannic acid, waxes, and fats.

Amylolytic bacteria

They are essential for starch breakdown. Among them certain species of *Bacillus* and *Clostridium* are able to break down starches, and the speed of the breakdown will vary according to the chemical composition of the different molecules constituting the starch, particularly the percentage of amylopectin present. Amylopectin is a branched compound and is the component that is the slowest to be broken down by bacteria.

Lipolytic bacteria

Relatively few genera are able to break down lipids, resulting in the production of lipase (a specific esterase that hydrolyzes the ester bonds between glycerol and the fatty acids), but among these particular mention must be made about *Bacillus*, *Alcaligenes*, *Staphylococcus*, and *Clostridium*. These microorganisms are able to degrade artifacts in which fatty substances are present as natural components (e.g., in wood) or else introduced during artifact manufacture (e.g., pastels).

Denitrifying bacteria

These are anaerobic bacteria that are relatively easily found on the surface of artifacts, provided organic substances are present. In fact, they are facultative anaerobes and metabolize the substrate by means of aerobic respiration in the presence of oxygen; however, to reduce nitrates they require anaerobic conditions. They can also utilize other electron acceptors such as the ferrous ion (Fe^{3+}). The biodeteriogenic activity of denitrifying bacteria is, in all respects, similar to that of other heterotrophic bacteria and is always bound to a specific enzymatic activity (amylase, protease, and esterase) and the production of catabolites such as organic acids, regardless of whether metabolism occurs in aerobic or anaerobic conditions (*Bacillus denitrificans*, *Pseudomonas stutzeri*, *Achromobacter severina*, etc.).

Fungi

Eumycota

They are eukaryotic organisms that are heterotrophic and are characterized by the presence of a rigid cell wall made principally of chitin; they belong to the kingdom of Fungi or Mycota. Fungi play an important role in the degradation of cultural heritage as they act either directly on organic materials that are utilized nutritionally or indirectly on materials of an inorganic nature that, although not metabolized directly, can nevertheless have organic fractions able to support fungal growth. In addition, fungi adapt easily to varying environmental conditions, and this means that environments for the conservation of artifacts of a historical and artistic interest, for example, hypogean environments, churches, museums, libraries, and archives, can provide ideal habitats for their development. In fungi with a pigmented mycelium (e.g., *Dematiaceae*), melanin is present. This confers the fungi with a resistance to numerous chemical and physical agents such as reducing substances, UV radiation, gamma and X-rays, and attack by enzymes. This resistance can be explained by the chemical nature of melanin, a quinone and hydroquinone combination that limits the damage caused by the formation of free radicals. However, the presence of melanin in the cell wall also seems to play a fundamental role in biodeterioration processes affecting stone in that it favors the penetration of the fungus into the substrate.

Many fungi such as *Cladosporium* have wide metabolic diversity and are able to flourish even in conditions of oligotrophy (scarcity of nutrient presence). Thus, they have often been identified as the fungi responsible for fresco degradation, the particles on the fresco surface representing the sole organic source. Degradation caused by microfungi, which in the case of artifacts of an organic origin often coincides with the degradation of the artwork itself, is due to the production of intracellular and extracellular enzymes specific to the individual substances to be consumed. Furthermore, the development of mycelium on a material, namely on the artwork, can also give rise to physical and mechanical damage caused by hyphae penetration. It must be noted that the term microbially-induced corrosion, rather than biodeterioration, is used for fungal deterioration of non-organic materials where mechanical damage is caused by mycelium growth or impact of secondary metabolites. The term biodeterioration is reserved for the deterioration process induced by microbial enzymatic activity.

Meristematic fungi

Among the fungi, meristematic fungi are of particular interest in stonework biodeterioration processes. Black fungi of meristematic growth (or microcolonial fungi (MCF)) are a broad and heterogeneous group of microorganisms, grouped together because of their ability to grow meristematically and to produce a melanin pigment, generally olive-black in color.

Both the production of melanin and meristematic growth endow the cell with resistance to extreme environmental conditions such as strong sunlight and water and nutrient scarcity, conditions frequently encountered by artwork in stone that is left out in the open in Mediterranean regions. Black fungi with meristematic growth form small black colonies (60–100 μm in diameter) on rocks and grow very slowly (1–2 months) both under natural conditions and in the usual culture media. Moreover, they are extremely versatile and are able to grow on the most varied substrates, as well as in oligotrophic conditions. Such fungi are resistant to environmental stress such as high temperatures ($>100^\circ\text{C}$), as well as to prolonged periods of UV radiation exposure and osmotic stress (up to 40%). It is also important to consider the deterioration actions of organisms like insects, rodents, and birds on art objects made using different materials.

Up until now, microorganisms on cultural heritage have generally been considered to be connected to actions of alteration. However, it was recently demonstrated that some microorganisms can be used in biocleaning and biorestitution procedures to remove harmful compounds from artistic objects. For example, the sulfate-reducing bacteria, *Desulfovibrio vulgaris*, has been used to remove a black crust containing sulfates and specific heterotrophic bacteria, *P. stutzeri*, to remove glue from frescoes. In addition, such bacteria can also be employed in calcite bioprecipitation for the conservation of monumental stone and for stone reinforcement.

Phototrophic microorganisms

This group includes algae and cyanobacteria and there is remarkable diversity in the organization of cells and vegetative structures. Algae are eukaryotic cells, exhibiting a full range of pigments (chlorophylls, carotenoids, and phycobilins), highly specific reserve materials, and wall components that can be used as discriminating elements during placement within systematic classification. Cyanobacteria are prokaryotic organisms linked to the kingdom of Eubacteria, and are able to carry out photo-metabolism similar to that of higher plants. They colonize archeological remains, stonework, frescoes, wall paintings, and mosaics, producing chromatic alterations, patinas, and biofilms of different colors (green, gray, orange, brown, and violet-red). Their deteriorative action is seen not only in aesthetical damage but also in chemical damage, because of substrate corrosion. Cyanobacteria can be divided into epilithic, growing on the surface of the stone, chasmoendolithic, in the fissures and cavities of

the stone but in contact with the surface, and endolithic, inside the stone itself. The genera of algae most frequently referred to in the biodeterioration of stone belong to the division *Chlorophyta*. The matrix may form a structured sheath called a sheath, capsule, or calyx, or else simply be an amorphous mucilage. It constitutes a fundamental characteristic for the colonization and the survival of the organisms: It permits adhesion to the substrate, functioning as a water reserve as it slowly swells with water and then gradually releases it, allowing the organism to overcome periods of adversity, inhibits predation, and, most importantly, it is the cement that holds together the microbial cells, thus giving rise to the formation of the biofilm. Investigations carried out on stone monuments have shown that most of the cyanobacteria present are forms endowed with a gelatinous matrix. The chemical nature of such a matrix, generally made up of negatively charged polysaccharides due to the presence of acid groups, can also contribute to the deterioration of the stone through complex-forming processes and leaching of the constituent elements; it also represents a source of organic material that supports the growth of the nutritionally more demanding heterotrophic microorganisms.

Lichens

The most frequent organisms found on stone monuments in an outdoor environment are the lichens. They tend to enrich environments lacking in biodiversity, for example, archeological sites and urban centers, but can also be agents of chromatic alteration and surface biodeterioration. Lichens, small symbiotic ecosystems formed by a fungus (mycobiont), depend nutritionally on photosynthetic partners (photobionts). In addition to their biodeteriogenic action, lichens can also play a bioprotective role: In fact, in the presence of high atmospheric pollution levels, they provide an effective barrier against pollutants that attack the mineral components of a substrate.

Bryophytes

Bryophytes are photosynthetic eukaryotic organisms that can play a significant role in the biodeterioration of materials, especially stonework, as they penetrate the substrate by means of rhizoidal structures that cause physical and mechanical damage. Like algae and lichens, many moss species can be considered pioneer organisms as they can colonize exposed rocky surfaces, and in a few cases are able to survive high temperature levels and radiation from the sun as well as long drought periods. Because of their capacity to survive in a latent form, and return to normal metabolic activity with the restoration of favorable conditions of humidity, Bryophytes are also considered poikilohydric organisms.

Vascular plants

They are an important consideration in biodeterioration processes. Indeed, their roots form a complex system that, during growth, can exert considerable pressure on a substrate. In the event of the substrate being ancient walls, architectural structures, monuments, or hypogeum chambers, root growth can result in severe physico-mechanical damage.

Materials Related to Cultural Heritage

Considering the most accepted and first proposed definition of biodeterioration by Hueck (1965) as “any undesirable change in the properties of a material caused by the vital activities of organisms”, it is important to illustrate the different kind of materials that can be attacked (Allsopp et al., 2003).

Materials are any form of matter, with the exception of living organisms, that are used by humankind, and all materials have an intrinsic value and thus there is an important economic dimension to biodeterioration. Our cultural heritage is made up of almost all types of materials, both natural and artificial, organic (that may be natural, semisynthetic, or synthetic compounds) and inorganic, and include stone, metals, textiles, paper, wood, and so on; in more recent times, photographic documents and magnetic and optical carriers have been introduced and widely established all over the world.

The biodegradation of organic materials is an essential process in the environment that helps in recycling complex organic matter and is an integral component of life. However, biodeterioration which mechanisms are similar to biodegradation also destroys historical structures, resulting in the loss of valuable cultural properties stored in libraries, archives, and repositories. Many enzymes break the bonds of polymers; some polyesters are degraded by lipases and esterases, proteins by proteases, starch by amylases, and cellulose and cellulose derivatives by cellulases. The organisms that pose major concerns to memorable heritage objects are microorganisms (bacteria, fungi, yeasts, and algae) and insects.

The biodeterioration of inorganic materials used in the works of art is essentially a process that involves monumental rocks and archeological remains, glasses, and metals. These cultural heritage objects are influenced by environmental parameters, which can modify their structure and composition by biological mechanisms. As already cited, the main types of damage derived from metabolic activity of organisms are associated with physical, chemical, and aesthetical mechanisms, while the intensity of damage is strictly related to the type and dimension of the organism involved, the kind of material and state of its conservation, environmental conditions, microclimatic exposure, and the level and types of air pollutants (Fig. 3). Information on materials related to cultural heritage, separated on the basis of the inorganic, organic, and composite materials, are reported.

Inorganic Materials

Historical stone objects (sculptures, buildings, and rocks) and frescoes

Deterioration of building stone begins from the moment it is quarried as a result of natural weathering processes. Other factors, sometimes acting synergistically, including a progressive dissolution–crystallization of soluble salts, pollution, and biological colonization, can accelerate natural deterioration of the mineral matrix. Decay is a consequence of the weathering action of several physical, chemical, and biological factors. In the case of calcareous stones, the materials, due to calcite leaching, increase their porosity in time and decrease their mechanical characteristics. All building walls contain soluble salts, dispersed within the porous materials or locally concentrated. These salts are solubilized and migrate with the water in and out of the stone. The drying out of the solution at the exposed surface results in the formation of efflorescences. Moreover, climate plays an important part in influencing the activity of organisms on stone in monuments and other objects of cultural value. The presence of living organisms on stone increases its susceptibility to damage through their water-binding capacity. Then, the mineralogy, porosity, surface roughness, and capacity to collect water and organic materials control its bioreceptivity and tendency to biodeterioration. However, environmental factors such as temperature, light intensity, pH, and relative humidity affect the number and type of colonizing species and hence the progress of colonization. Different hygroscopic salts (carbonates, chlorides, nitrates, sulfates, etc.) can be found on the surface of decayed monuments, which have extremely saline environments. Halotolerant bacteria and Archaea can grow in many different niches including deteriorated mural paintings; the detection and identification of an Archaeal community by DNA extraction, fragment amplification with specific primers using denaturing gradient gel electrophoresis (DGGE) of PCR-amplified DNA encoding 16S rRNA, confirm important ecological implications of Archaea on monuments because of the considerable production of efflorescences. Water is very important in causing the mechanical degradation of stone, assessed mainly by porosity and bulk density, while its circulation through stone is controlled by its porosity size, distribution, specific surface, and capacity. Rainfall intensity and amount greatly influence erosion rates of marble and limestone, with a minor effect on sandstone. The presence and amount of water control biological activity and growth; moreover, hydrodynamic forces bring microorganisms (i.e., bacteria) close to substrates and their sorption onto solid surface induces the formation of extracellular polymeric substances (EPS), biofilms, and patina.

Patina includes many environmentally induced surface changes such as oxalate film, lacquer, crust, deposit, karst, rock varnish, microstromatolite, efflorescence, carbonate, gypsum, iron, manganese, oxalate and silica skin, and others. The formation of patina is a very complex process. Since it takes a very long period of time to develop, the patina itself is often seen as an object of historical interest. The main process can be summarized as an exchange of matter and energy between two open systems: the solid matrix and the surrounding environment (indoor or outdoor atmosphere, water soil, an intermediate cover of plaster or paint). The formation of patina can come to a standstill under environmental conditions. However, in cases in which patina formation becomes a historic evolution of the surface area of a monument, the real danger is in the addition of new layers on historical deposition on top of the original material. These deposits (crusts, skins, sinters, gypsum crust, etc.) may represent an increasingly dangerous hazard for the original material they cover; in fact, the mass increase may lead to fissures, exfoliation, and loss of the original surface material. Among the additional factors that accelerate deterioration of stone, the effects of anthropogenic sources of pollution on building stone are still to be definitively characterized. An example of particular interest is the formation and constituents of black crusts (Fig. 4).

It has long been acknowledged that burning of fossil fuels has led to an increase in the concentrations of acid gases in the atmosphere; of these, perhaps the most important is sulfur dioxide, which forms sulfurous acid when dissolved in water (acidic rain). Sulfurous acid is oxidized to sulfuric acid, which in turn reacts with calcium carbonate to form calcium sulfate, the mineralized form of which is known as gypsum. The formation of gypsum then leads to the creation of cavities below the surface as a result of migration of calcium ions to the surface. Thus, if soluble gypsum is washed away, it takes with it some of the stone itself, initially causing loss of surface details but eventually leading to loss of structural integrity. Particulate matter from the atmosphere can combine with gypsum to leave unsightly black crusts on the surface of the stone. Carbonaceous particles were

Fig. 4 Black crust patinas on marble surface lunetta (Milan Cathedral, Italy). Photo: G. Ranalli, E. Zanardini.

thought to be the most significant element in black crusts, but they also contain a complex mixture of aliphatic and aromatic carboxylic acids and polycyclic aromatic hydrocarbons. Finally, stones in urban areas act as 'passive repositories for any kind of gaseous and particulate air pollutant present in the surrounding atmosphere'.

Glass

Glass is a ceramic material (solid, inorganic, and nonmetallic) obtained by vitrification (fusion and cooling without crystallization) of primitive substrate (amorphous silicate, about 70%) and by adding several agents for fusion, stabilizing, decoloring, coloring, and so on. The exact origin of glass is still unknown, but there exist objects dated 1700 BC from Mesopotamia. The biodeterioration of glass is related to several factors, including both the glass composition and the environmental conditions on exposure. Although preliminary case studies of glass biodeterioration date back to the early nineteenth century, the phenomenon is understood only now. The presence of fungi, bacteria, lichens, and algae as biodeteriogen agents poses a serious problem for the glass surfaces found inside damp ancient structures. Free silicon bonds can react with organic acids produced by specialized microorganisms, which are capable of growing on the glass surface and finding nutrients for their metabolism (acidic attack), on glass surfaces. A hazard is the alkaline attack leading to the rapid destruction of the Na reticulum of the glass, accompanied by silicon release. This process is accelerated by temperature and exists even when glass is exposed to the air, but not for a long time. Glass may be severely damaged by biodeterioration because of initial fungal attack that leads to etching, increase in opacity, and the presence of black spots on the surface of glass. Among the bacteria capable of colonizing objects in glass, the iron bacteria (*Sphaerotilus* and *Gallinella*) and the sulfur-oxidizing bacteria play an important role in the metabolism of sulfur and manganese, respectively. In marine environment, algae and bacteria can play an important role inducing phenology of more alterations in glass as surface erosion, microfractures, and pitting. In other cases, isolated bacteria related to the genus *Flexibacter*, exhibit their capability to grow on the surface of glass and adapt to an oligotrophic environment and to develop themselves inside a thin layer of biofilm produced by other microorganisms.

Metals

Deterioration of metal materials appears as a complex matter from the physical, chemical, and biological points of view. Their specific mineralogical, structural, mechanical, and electrical properties are further influenced by the fact that metal materials utilized in the artistic fields are represented by alloys from the fusion of a single metal with almost another element (e.g., ancient bronze, made of copper and tin). All metal materials, except gold, are chemically reactive in the presence of compounds present in air, soil (O_2 , CO_2 , SO_2 , salts, etc.), and, electrochemically, in water and moisture. Chemical corrosion of metals occurs when the structural elements undergo a chemical change, transitioning from the ground state to an ionized state. The phenomenon consist of two equivalent reactions, for example, for a ferrous metal in an aqueous oxygenated environment: $2Fe \rightarrow 2Fe^{2+} + 4e^-$ anodic reaction, oxidation $O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$ cathodic reaction, reduction.

In the absence of oxygen, either hydrogen ions or water is reduced at the cathode: $4H^+ + 4e^- \rightarrow 2H_2$ or $2H_2O + 4e^- \rightarrow H_2 + 2OH^-$

Microbial activities can influence the above reactions (biocorrosion), but the basic mechanism is still electrochemical. The microbially influenced corrosion (MIC), estimated as 20% of all metal corrosion, is generally associated with the microbial colonization of the metal surfaces and the formation of nonhomogeneous biofilms; the resulting surface appears as a pitting corrosion (biopitting) where the microbial metabolites, CO_2 , S, H_2S , NH_4^+ , and acids (citric, oxalic, succinic, and fumaric), are the responsible agents. Aerobic and anaerobic bacteria are the major microbial groups involved in metal biocorrosion.

Under aerobic conditions, the sulfur-oxidizing bacteria related to genus *Thiobacillus* can oxidize elemental sulfur to obtain energy, solubilize metals producing sulfuric acid, which is highly corrosive. Metal biocorrosion by *T. ferrooxidans* and *Thiobacillus thiooxidans*, *Metallogenium* spp., *Sulfolobus* spp. is a serious problem, for example, in acid mine waters where, in presence of Fe^{3+} ions, the pH value drops to between 2 and 3, causing ferric sulfate deposition and finally severe corrosion in concrete and pipes.

Under anaerobic conditions and in a reduced environment with redox potential higher than -100 mV, the sulfate-reducing bacteria (SRB) related to genera *Desulfovibrio* and *Desulfotomaculum* produce H_2S , which is highly corrosive, inducing precipitation of metal sulfur salt. In the presence of iron ions, the overall reaction, where FeS and $3Fe(OH)^{2-}$ are final corrosion products, is as follows: $4Fe + SO_4^{2-} + 4H_2O \rightarrow FeS + 3Fe(OH)^{2-} + 2OH^-$

Organic Materials

Paper

Its invention is usually credited to a Chinese court official, Tsai Lun, in about AD 105. In the eighth century paper was produced in the Middle East by the Arabs. Papermaking techniques were slightly changed by the Arabs, who introduced linen into the raw material and the use of paper mills. The art of papermaking gradually spread and in the twelfth century paper became the most common writing material in the West as the Europeans learnt the art from the Arabs. The principal compound in paper is cellulose, which is made of vegetable fibers. Until the nineteenth century, pure cellulose was mainly obtained from rags generally made of linen, hemp, and cotton. The handmade process consisted of converting the cellulose into pulp. After dispersion in water, the pulp was drained through a mold, dried, and pressed to form sheets. As the demand for paper grew, wood became the main raw material from the nineteenth century. Fibers were then obtained either by mechanical or by chemical processes. So, the composition of paper changed from almost pure cellulose to cellulose and significant amounts of hemicellulose and lignin. However, the production of a paper sheet also needs other compounds. For example, in order to reduce the spread of ink, the paper surface needs to be filled, the most used sizing materials being starch, gelatin, resin, and various synthetic polymers. Fillers, such as clays or chalk, are added to fill the pores and make the paper opaque. Other products used during papermaking include dyes, pigments, and fluorescent whitening agents.

The scientific and conservation literature claim that paper is an easy source of organic carbon for microorganisms. Paper biodegradation is well known. A major concern related to fungal colonization is pigment that may stain the substrate. Some pigments are soluble in certain solvents and can be removed through the application of a specific solvent. In addition, some permanent discoloration may also be caused by weak acids produced by fungi. Interestingly, there is one type of degradation named foxing that is still not fully understood. Some foxing stains are claimed to have a biotic origin and others an abiotic one. Foxing is a deterioration of paper occurring as brownish, reddish stains that could be the result of the activity of microorganisms or the oxidation and/or formation of heavy metals deposits. After many years of research and discussion, it is believed that the majority of foxing stains are due to microorganisms. Some microbial growth is presented in the Fig. 5.

Fig. 5 Scanning electron micrograph of microbial growth on paper. Photo: T. Lech.

Wood

The most serious damage to wooden objects in indoor environments (museums) is caused by insects; they utilize wood as a nutrient source and for depositing eggs. Many insects (Coleoptera and Lepidoptera orders) use as substrate cellulose, as they have microorganisms in their gut that supply the cellulase enzyme. In an outdoor environment, when the moisture content of the wood is above 20%, it becomes susceptible to microbial attack by microfungi and bacteria. The predominant fungal infections, by exoenzyme production and subsequent destruction of natural polymers, are white rot (*Fomes* sp., and *Pleurotus* sp.), brown rot (*Poria* sp., *Merulis* sp., and *Coniophora* sp.), and soft rot (*Chaetomium* sp., *Alternaria* sp., and *Humicola* sp.). Because both bacteria (*Pseudomonas* sp. and *Achromobacter* sp.) and Actinomycetes (*Micromonospora* sp.) require a higher water content, their role is important in outdoor and marine environments.

Papyrus

The papyrus plant belongs to a widely distributed family of plants found in wet environments in tropical and subtropical areas. Papyrus was the material used by ancient and classical civilizations to write their texts. The raw material of papyrus comes from the pith of *Cyperus papyrus*, the largest member of the family. The papyrus pith is composed mainly of cellulose (54%–68%) and lignin (32%–24%); the proportions are principally based on age, manufacturing process, and environmental effects. It is worth noting that papyrus contains more lignin and less cellulose than paper and also contains uronic acid. The papyrus-cementing material is a polymer whose monomers are galactose, arabinose, and rhamnose.

Papyrus samples from different museums in Cairo were isolated and degrading microorganisms were identified. Some were tested for their cellulolytic activity, and it was found that the cellulose was attacked by all *Chaetomium* fungi that attack cellulose as well as by *Emericellopsis minima* and *Botryodiplodia theobromae*. In particular, *Chaetomium globosum*, *Chaetomium ochraceum*, and *Chaetomium elatum* along with *E. minima* intensely depolymerized cellulose with values ranging from 76% to 100%. The majority of microorganisms are able to hydrolyze the sugars dl-arabinose and l-rhamnose. Papyrus may be completely decomposed by fungi (genus *Chaetomium*) or Actinomycetes; the latter are especially dangerous when the conditions are unsuitable for other microorganisms, as in the desert. *Penicillium* is very often detected on paper but high temperature does not favor its growth. The order of the utilization of inorganic nitrogen sources is ammonium nitrate, ammonium phosphate, ammonium sulfate, and sodium nitrate. Ammonium nitrate represents a good source of nitrogen as nitrogen is present as ammonium and nitrate ions. The suitable temperature for fungal growth, under slightly acidic pH and relative humidity of 95%, is 24–30°C, but it is 42°C for only seven species.

Parchment

Perhaps, parchment was invented in the second century BC in Pergamum, or probably known 100 years before; parchment replaced papyrus almost completely from the third or fourth century AD. Parchment had many advantages, especially over papyrus. It was

Fig. 6 Scanning electron micrograph of bacterial growth on parchment. Photo: T. Lech.

Fig. 7 Scanning electron micrograph of fungal growth on parchment. Photo: T. Lech.

stronger and more durable than fragile papyrus and the raw materials for making it, animal skins, were available everywhere and not limited to one geographic location, namely Egypt. Parchment could be written on both sides (*recto* and *verso*).

Collagen is the major component of most connective tissues in animals and therefore is the bulk material for parchment. The main distinction between parchment and leather is that parchment preparation involves drying the wet skin while under tension. In contrast, the properties of leather are mainly due to the addition of tanning agents. As for the other supports, the susceptibility of parchment to microbial deterioration is dependent on the raw material, methods of production, and conditions of preservation. The most active microbial agents that cause damage to parchment belong to the genera *Streptomyces*, *Cladosporium*, *Scopulariopsis*, *Fusarium*, *Sporendonema*, *Ophiostoma*, *Aspergillus*, *Mucor*, *Penicillium*, *Nocardia*, *Alternaria*, *Trichoderma*, *Botryotrichum*, *Acinetobacter*, *Micrococcus*, *Bacillus*, *Peanibacillus*, *Staphylococcus* and *Serratia*. The biodeterioration of these materials (parchment and leather) was mainly caused by fungal attack. In contrast, the increase in the pH during the deacidification treatment, generally necessary for parchment with a pH value lower than 5, by using ammonia greatly increased the microbiological deterioration suffered by parchment. Some bacterial and fungal growth are presented in the Figs. 6 and 7.

Biodeterioration of these materials (parchment and leather) was mainly due to fungal contamination, and less due to bacterial contamination. However, bacteria with proteolytic activity and in particular collagenolytic activity were sought and most of the isolated strains were able to grow on media containing collagen or parchment as the sole source of carbon and nitrogen. SEM observations demonstrated that the bacteria colonized subsurface layers along the collagen fibers. Among several biocides, Preventol R-80 and Catamin AB proved to be the more active biocides. In addition, mixed treatment using gamma radiation after a 3% pretreatment with Catamin AB is suggested. However, it should be noted that the list of legally permissible biocides in the conservation of cultural heritage objects is reduced from one year to another. As for historical parchments, the lack of a safe disinfection method is the greatest problem. It is therefore crucial to provide appropriate storage condition to minimize the risk of active microbial growth.

Textiles

Textiles have accompanied mankind for thousands of years and they have been used for a variety of purposes. Starting from their utilitarian aspect, they have been used as clothing, upholstery material and decorations. They have also performed a significant role in religious rites and diplomacy. As such, they constitute a significant and very specific part of our cultural heritage. The vast majority of historical textiles are made of natural fabrics, such as linen, cotton, wool or silk. The first recorded usage of natural fibers concern mainly those of plant origin, i.e., linen that dates back to the 7th century BC and cotton, the use of which was recorded in the 5th century BC. Usage of fibers of animal origin was noted slightly later: 7,000 years ago for wool in Mesopotamia and in the 3rd century BC for silk in China. However, collections of synthetic textiles, which are rather young and date back to the 20th century, are not without significance. Currently, conservators make every effort to preserve historical textiles for the future generations in the best

Fig. 8 Scanning electron micrograph of microbial growth on silk. Photo: T. Lech.

condition possible as they constitute unquestionable heritage and evidence of not only technological, but also artistic, religious and diplomatic activity of former communities.

As any historical materials, textiles, particularly those made of natural fibers, undergo constant deterioration. Processes of destruction and decomposition may be triggered by various environmental factors, such as UV exposure, too high or too low relative humidity and temperature, oxidation and hydrolysis processes, as well as destructive effects of microorganisms and insects. Textiles of natural fibers, most of them showing organic polymer structures, are particularly prone to biodeterioration. Microorganisms, both fungi and bacteria capable of producing appropriate enzymes, may use natural fibers as a source of carbon for their development. Initially, microbial growth on textiles might be associated with esthetic changes (staining or discoloration). Later, microorganisms may decrease fiber resistance and cause their thinning, thereby leading to their complete destruction. As has been mentioned earlier, active microbial growth is dependent upon specific environmental conditions: relative humidity, temperature, adequate pH or presence of carbon sources in the form of organic contaminations. Also, it must be underlined that any mechanical fiber defects that have occurred during their use and further storage have a significant impact on their susceptibility to be settled by microorganisms.

Silk items constitute a considerable part of historical textile collections. This is mainly caused by their lower susceptibility to biodeterioration. Silk is mainly made of fibril proteins creating long fibroin chains of a high crystallization degree. Fibroin filaments are connected with one another with sericin, which was usually discarded during silk production. Another textile of animal origin is wool. It is also composed of protein fibers derived from hair of various animal species. The structure of wool fibers is more cellular in nature, and it is mainly composed of keratin. However, the outer layer of these fibers is coated with a protein membrane that also contains waxes and fatty acids, which constitute additional protection of the fibers thanks to their hydrophobic properties. The most common bacteria isolated from animal-origin textiles include strains of the following genera: *Aeromonas*, *Bacillus*, *Micrococcus*, *Pseudomonas*, *Proteus* and *Streptomyces*, whereas the most common fungi include: *Acremonium*, *Alternaria*, *Aspergillus*, *Chaetomium*, *Chrysosporium*, *Cladosporium*, *Ctenomyces*, *Fusarium*, *Penicillium*, *Phoma*, *Torulopsis*, *Trichoderma* and *Trichophyton*. Some microbial growth on silk is presented in the Fig. 8.

The main constituent of plant-origin textiles is cellulose. It is a polysaccharide, a linear cellobiose polymer, that is made up of a crystalline region, which is significantly more resistant to biodeterioration, and an amorphous region, which is more readily attacked by microorganisms and is a site where cellulose fiber deterioration usually begins. Microorganisms that are most frequently isolated from historical textiles of plant origin or places of their storage are: *Bacillus*, *Cellulomonas*, *Cellvibrio*, *Clostridium*, *Micrococcus*, *Peanaibacillus*, *Pseudomonas*, *Streptomyces*, *Alternaria*, *Aspergillus*, *Chaetomium*, *Fusarium*, *Memnoniella*, *Myrothecium*, *Neurospora*, *Penicillium*, *Scopulariopsis*, *Stachybotrys* and *Trichoderma*.

An additional difficulty in preserving textile collections lies in the fact that a large part of such textiles, especially historical ones, e.g., liturgical vestments, are made of various natural fibers, which provides a source of nutrition for a vast range of microorganisms. These microbes may cooperate with one another and rapidly lead to textile destruction. Historical textiles are

stored in museums, galleries and private collections. However, lots of such items, being a unique collection of liturgical vestments, are stored in sacristies and church treasuries that are historical buildings themselves and not always assure appropriate storage conditions.

Composite Materials

Paintings

Paintings, including easel and mural objects, contain a wide range of organic and inorganic compounds, many of which are biodegradable by a large variety of microflora. Additives such as glue, emulsifiers, and thickeners are used to prepare the support, to facilitate the application of paint layers, or to increase the final esthetic object. In easel, the organic components of the paintings are sugars, gums, polysaccharides, proteins, oils, waxes, and undefined mixtures such as egg yolk. In mural paintings, pigments are mixed in oil and water, in the presence of casein or milk, in order to guarantee better adhesion on the plaster. This implies that microorganisms can grow inside different ecological niches on several substrates. The biological attack on these materials occurs in confined environments only under poor conservation conditions such as high humidity level, soil contact, poor ventilation, and rare maintenance operations. Moreover, the differences in the materials used and the chemical nature of the substrate may influence different evolution of microbial taxa colonizing works of art. Several studies on microbial succession in mural paintings show that bacteria can be considered among the first colonizers of frescoes, able, in some cases, to oxidize inorganic elements like lead present in pigments, and leading to the formation of lead oxides that cause damage by changing color (brown-black spot production). Moreover, the most frequent bacterial species present are members of the genus *Alcaligenes*, *Bacillus*, *Flavobacterium*, and *Pseudomonas*. Fungi normally are considered secondary colonizers. However, when frescoes in hypogean sites (tombs and grottes) are excavated, the predominant species isolated are members of the order Actinomycetales (genera *Streptomyces* and *Nocardia*); then, in very short time (months), photosynthetic bacteria, fungi, and algae become associated with the first colonizers, conferring typical colored crusts (green to black stain); these phenomena are quite evident after exposure to air, on illumination, and when hypogean rooms are open to visitors. Many are the mechanisms of aggression and microbial successions on paintings. Generally, microorganisms colonizing paintings and frescoes may be effected by environmental conditions and by the presence and concentration of atmospheric pollutants, especially sulfur dioxide. The sulfuric acid present in air containing moisture dissolves calcium carbonate in works of art (fresco, plaster, and stone) and leads to the precipitation of dihydrous calcium sulfate (gypsum). Gypsum deposition, by the formation of white crystal aggregates, is usually responsible for efflorescence, and for colonization by sulfur-oxidizing bacteria that cause direct and indirect mechanical damage such as the detachment of portions of painted layers. This is true if we consider that the death and lysis of these bacteria provide the organic substrate necessary for heterotrophic bacteria and fungi.

Photography

Photography is a method that produces a visible image by the interaction of light with silver halide salts contained in a binder applied to a substrate. Photographic materials include still and moving images and microfilms; many other different methods have been introduced and used since 1831. However, from a microbiological point of view, it is very interesting to know about the materials that photographic materials are made of. Photographic supports can be made of metals, for example, a copper plate covered with a fine silver layer as in the daguerreotype or a black varnished metallic plate as in the ferrotype; glass as for the collodium plate; paper, typical of calotype and albumin print; and, finally, semisynthetic and synthetic polymers, including cellulose nitrate, cellulose acetate, and polyethylene terephthalate. The light-sensitive materials are silver halides: silver chloride, silver bromide, and silver iodide. Other important photographic materials are binders such as collodium, which contains cellulose nitrate, albumin, and gelatin, sensitizers, antifoggants, and hardenings. Gelatin is the most satisfactory binder in terms of cost, chemical processing, and physical and optical features. Fungal attack is the main form of biodeterioration that occurs in photographic materials. The presence of substances of animal origin such as albumin and gelatin represent an important source of nutrition for microorganisms, in particular fungi that cause, for example, an increase in gelatin solubility in water. Thus, water or water solutions should not be used to clean photographic materials containing gelatin when there is a fungal attack. The use of cotton soaked in adequate film cleaner is suggested. In addition, the contact between fingers and photographic documents should be avoided as salts in the fingerprints absorb moisture and create favorable conditions for fungal growth. The Krieger collection includes thousands of glass plate negatives made in the years 1880–1926: Several glass negatives showed fungal contamination, and among the isolated fungi, *Aspergillus nidulans*, *Aspergillus versicolor*, *Cladosporium cladosporioides*, *Penicillium cyclopium*, and *Penicillium janthinellum* were the most frequent.

Photographic prints were protected against microflora by immersing the prints for 3 min in 0.5% water solution of sodium salt of 4-chloro-3-cresol. For both black-and-white and color films and prints, fungicidal treatment by immersion in 1% solution of zinc fluorosilicate yields positive results. Use of activated film coating reduces scratches, fungal growth, and color dye fading, where humidity control of storage environment is not feasible. On microfilm objects based on cellulose acetate and polyester, the susceptibility to biodeterioration and subsequent isolation and identification of biodeteriogens showed the presence of *Aspergillus niger*. Different species and strains of fungi contaminate microfilms. One way to prevent fungal and insect attack is either to hermetically seal the photographs in laminated envelopes or to laminate/encapsulate the photograph in plastic. However, the best method to prevent fungal deterioration of photographic material is to keep it in a cool, dry, and dark place.

Magnetic tape, optical disk

The magnetic tape is made of a thin magnetic layer that comprises magnetic particles, such as iron oxide and chromium dioxide suspended in a lubricant, and a polymer binder (generally a polyester- or polyether polyurethane-based system). The most commonly used tape substrate is polyethylene terephthalate. Among several sources of damage (heat, light, grit, moisture, and atmospheric pollutants), microbial growth is considered a main concern for the preservation of magnetic media. The most frequently isolated fungi belong to the genera *Alternaria*, *Aspergillus*, *Chaetomium*, *Penicillium*, and *Stemphylium*, and these have been detected on floppy disks in tropical countries and also in temperate countries under humid conditions. Many of these microorganisms are widespread fungi that are able to grow on a variety of products. For the prevention of fungal growth on videotape, it is recommended that the interior of the tape container and the edges of the tape itself be checked for black, brown, and greenish stains that might indicate the presence of fungi. Moldy tapes should not be used until the microorganisms have been eradicated. Recent experiences suggest that the material should be placed in a desiccating container and after equilibrium is reached the surface should be vacuumed. After this treatment, the film can be cleaned with a chlorinated solvent cleaning machine. However, the use of a UV source, except for some black and white films, is not recommended as UV damages dyes.

Compact disk (CD-ROM) and digital versatile disks (DVDs) introduced into the market are based on an improved polymer, made of aromatic polycarbonates, more durable than aliphatic. CD producers generally do not care about biological deterioration of CDs. However, a fungus of the *Geotrichum* type was able to grow on a common CD under tropical conditions (about 30°C and UR 90%). Biodeterioration occurred as bioturbation traces. A fractal structure and the destruction of the pits, which in turn means the loss of the information stored in the disk, were observed. It is worth noting that *Geotrichum* is a very common genus commonly found in food products, water, and animals, and it has also been isolated from air. Thus, fungal growth is not related to a particular geographical area but to the environmental conditions that permitted the growth.

Methods of Control and Prevention

The microbial contamination of cultural heritage is still an underestimated concern. One reason may be the difficulty in establishing a definitive causative relation between the biological agents and the damage to materials, especially in those cases where there is damage but not much biological growth.

The prevention of biodeterioration of a cultural heritage includes all the operations needed to avoid the growth of microorganisms and a consequent biological attack by biodeteriogen microorganisms on the materials composing the heritage. These so-called indirect methods do not act directly on the microorganisms but hinder or slow down biological growth, modifying where possible the environmental conditions so that they become unsuitable for biological growth. Because of the close environmental relationship and dependence between the biological species and the environment, the most efficient and easily realized methods for impeding undesirable growth act on the causal factors, particularly humidity, temperature, ventilation, light, that can inhibit or condition their presence. These factors cannot always be controlled, whereas it is possible to control the conditions of confined environments (museums, libraries, and churches). It is decidedly more difficult to control an external environment (monuments and archeological areas). In fact, whereas some parameters (light, humidity, and temperature) can theoretically be modified, nutritional factors present in the artwork when support the biological growth, cannot be changed without damaging the nature of the object itself. On the contrary, factors encouraging biodeterioration (dirt, dust, and deposits of varying kind) can be removed. It is not necessary to act on all the parameters that restrict biological growth and it is sufficient to lower or to raise just one of these until there is no increase. 'Direct' methods of biodeterioration control provide for direct action on the organisms, and this can vary.

Biochemical

Such methods use compounds of biological origin: Antibiotics (active at very low doses, but there is loss of effectiveness over time), enzymes (used especially for cleaning) and pheromones (used to induce males to leave the structures where they nest) are used for infestations in the deep layers of the material where biocides cannot penetrate.

Biological

These are methods that use antagonist or parasitic species to limit the growth of other animal or vegetable species. In the case of flora, phytophage insects can be used, while for animals, above all avifauna, the choice lies with predator species of eggs and the young to reduce the population density of the other species. Unfortunately, such actions are very difficult and are not usually used in the case of microorganisms with deteriorative potentials that might change and pose even greater threat to historical materials.

Physical

These methods foresee the use of X-rays with biocidal action or noxious gamma radiation and UV rays. Indeed, UV rays have low penetration and are thus not effective for alterations involving the interior of objects. The most problematic aspect of UV treatment

is bound to its ability to alter, from the chemical point of view, the treated materials (pigments, cellulose, and proteic materials) and to the difficulty of transporting the irradiating source *in situ*. Note that gamma rays have a greater biocidal activity than UV, but their application is limited to treating organic materials (paper, parchment, and wood), and is aimed more at resolving microflora disinfection problems than those connected to the presence of insects.

Mechanical

These methods foresee the removal of biodeteriogen organisms by the frequent use of manual instruments like scalpels, scrapers, spatulas, and so on. Nevertheless, they have the disadvantage of failing to guarantee results over the long term, in that it is very difficult to completely remove the vegetative or reproductive structures of the species present, at least without seriously damaging the surface of the substrate. In fact, on dealing with a fungal mycelium, a lichen thallus, or even with roots rather than a plant, it is rare for the colonization to be only superficial, so to avoid damage to the surface of the stone mechanical removal ends up being only partial. However, mechanical methods do have the advantage of adding nothing that can cause further degradation. Generally speaking, these methods can be used with chemical methods and can thus be very useful.

Chemical

Chemical methods foresee the use of synthetic chemical substances like pesticides and disinfectants, more generally called biocides. The requirements of products to be used in the conservation of artwork are high efficiency against biodeteriogens, absence of interference with the constituent materials, low toxicity for human health, and low pollution risk for the environment. Biocides must be employed with caution as they can react with the substrate and cause macroscopic effects like spots, yellowing and bleaching, and increased brilliance or opacity. In fact, the recent application of more accurate investigative methodologies showed how, in reality, many of these products produce negative collateral effects, though these are not always obvious. Furthermore, biocide substances can interact with other products used in previous restoration.

For protecting monumental stones, it is practically impossible to control weather variables, while for rock sites the construction of protective structures, preventing water runoff of surfaces, can effectively reduce biological growth.

In order to reduce biological risk for the organic objects maintained in confined environments, the control of temperature and relative humidity is frequently cited as the first step in environmental control especially in museums, archives, and libraries. Poor storage conditions impede their preservation. High relative humidity, for example, above 60%, along with high temperature encourage the growth of microorganisms. Damage to historical records due to bacteria and fungi can be reduced by limiting access of visitors to storage areas and monitoring the collections environment. However, it is worth noting that not only improper storage conditions but also disasters caused by water, such as broken pipes, leaking roofs, blocked drains and fire extinguishing, favor microbial growth, if a prompt action is not taken. In indoor environments, another important goal should be the monitoring of the microflora of the air throughout the year. This can then be used as a standard reference to determine changes that had happened in a building or a room. It is worth noting that a close similarity has been found between the aeromicroflora and the library and archival materials biodeteriogens. Another important issue is maintenance, such as dust removal; dust and dirt can contain spores and bacteria and provide the nutrients required for microbial growth.

No less important is the protection of workers from risks related to exposure to biological agents at work. In the past few decades, growing concerns about the use of chemical compounds have resulted in an in-depth evaluation of the effects of pesticides on human health and safety. Any process should be safe for the operator and the environment and no chemical residues should remain in the treated materials. The awareness of pesticides hazardous to human health and the environment has led to a search for alternatives. Among the main nonchemical treatment alternatives used for collections including freezing, gamma rays, microwaves, and modified atmospheres, only high-energy radiation can kill microflora. However, high-energy radiation is generally recognized as a harmful process for library and archival materials. Possible future alternatives can include biological control to stop the growth of harmful microorganisms and bioremediation/bio-recovery of cultural heritage. Of note is the fact that disinfection treatments are not neutral to historical materials and may cause further weakening of the structure of these frequently already deteriorated textiles. Moreover, further fiber weakening in combination with the elimination of microorganisms creates a niche that can be settled by microbes of even greater biodeteriorative potential. That is why decisions about any disinfection treatments should be made with caution and be based on both microbiological tests and the preservation status of a given item.

Molecular Methods in Microbial Hazard Identification

Microorganisms are capable of adaptation to various atmospheric conditions, thanks to which they can settle various environmental niches, even those unfavorable for development/life of organisms. Moreover, microorganisms may cooperate with one another, which additionally enhances their adaptation ability. That is why gaining full knowledge about the diversity and biodeteriorative potential of microbes settling historical objects or their storage environments is so important, particularly in protection of cultural heritage collections, i.e., historical items touched by time. Currently, there are a number of research methods that enable determination of a microbiological status of a given item and its storage environment. Despite their numerous advantages,

conventional microbiological methods aided with biochemical tests and light microscopy, which have been commonly used for years, do not allow full microbiological assessment. These methods are mainly based on culture techniques requiring adjustment of various environmental factors (temperature, humidity) or application of an adequate microbiological medium (pH, content of mineral salt, sugars, amino acids, etc.) in laboratory settings in order to grow the greatest spectrum of fungi and bacteria present in a test sample. Unfortunately, this is very difficult and, as noted in the literature, only 1%–5% of microorganisms present in a given environment can be isolated using culture methods. That is why it is vital to implement more accurate test methods in order to protect valuable collections of cultural heritage. This is where methods of molecular biology, in particular metagenomics, proteomics and metabolomics, can be helpful. The greatest advantage of the omics techniques is the ability to obtain a wide spectrum of information on, among others, microbial species diversity, their deteriorative potential or metabolic activity directly on the basis of samples collected from the environment. Tested material may be derived from samples taken from a variety of items, such as paper documents, parchments, textiles, leather, ceramics, glass, stone, wood etc., as well as samples of indoor air collected from storage rooms. Microbial species identification is usually performed by methods based on the polymerase chain reaction (PCR) technique. It enables amplification of selected fragments of genetic material. Genetic markers typically used for this purpose are DNA sequences conserved within ribosomal RNA (rDNA) gene: 16S rDNA is used for bacterial identification, and 18S rDNA for fungi. As for identification of filamentous fungi and molds, the non-coding internal transcribed spacer (ITS) sequences are also frequently used as a genetic marker. Their additional asset as a genetic marker is a large number of its copies in all fungi.

A slightly different research approach is creating genetic fingerprints enabling one to analyze biodiversity, trace genotypic structure changes in an environment, also including non-culturable microorganisms, and identify quantitative changes in microbial communities in a given environment. In the event of microbiological hazard to cultural heritage collections, the most common method is DGGE/TGGE (denaturing/temperature gradient gel electrophoresis). It consists in amplification of selected marker gene sequences (16S rDNA, 18S rDNA, ITS etc.), followed by separation of a PCR product mix in polyacrylamide gel with a denaturing agent. The outcome is a pattern of bands (a fingerprint), each of them corresponding to specific genotypes present in the environment. In this technique, the most common matrix is DNA obtained from the environment. Also, RNA can be used for this purpose, in which case the results include information on the expression of selected genes, e.g., those responsible for the production of cellulolytic or proteolytic enzymes. The usage of RNA as a matrix enables initial specification of microbial deteriorative potential in a given environment. Analyses using DGGE/TGGE have been successfully implemented in studies on biodeterioration of cultural heritage objects made of various materials, for example for testing diversity of microbial communities, including bacteria, cyanobacteria and actinomycetes and fungi. Environmental fingerprints can also be created using the following methods: SSCP (single strand conformation polymorphism), ARDRA (amplified rDNA restriction analysis), T-RFLP (terminal restriction fragment length polymorphism) and ARISA (automated ribosomal intergenic spacer analysis). In the recent years, the development of the next-generation DNA sequencing (NGS) techniques has been a breakthrough in metagenomic studies. Not only do these methods enable taxonomic identification of microorganisms in a test sample, but also allow phylogenetic and functional analysis of microbial communities. It must be emphasized, however, that methods based on next-generation sequencing deliver a vast amount of valuable information, which poses considerable challenges in its analysis and interpretation since advanced bioinformatics tools are needed. Nevertheless, research based on NGS and its further modifications will become the basis for investigations in the fields of ecology and molecular microbiology.

Protection of Cultural Heritage Collections

In the recent years, institutions protecting cultural heritage collections, such as museums, archives, galleries and libraries, have completely changed their attitude towards fulfilment of their crucial task. A considerably greater emphasis is currently put on undertaking preventive measures to protect historical objects from deterioration and damage. This approach is called preventive conservation. Among other things, it encompasses legal regulations and institutional principles, visitor movement management, sharing and loaning items, maintenance of appropriate climate conditions, minimization of biological hazards as well as ensuring appropriate protective containers and proper manner of storage. The monitoring of the inner climate should include, among others: Controlling relative air humidity, temperature, UV exposure, dust level (PM10 and PM2.5) or the presence of organic contamination. Furthermore, stable climate parameters are vital for assuring proper housing conditions of cultural heritage items. Such collections must be protected against abrupt temperature and humidity alterations in a short period of time. Also, periodical observation of items in order to detect alarming changes, particularly of the microbiological origin, is essential. Compared with remedial conservation, preventive conservation requires conservators to use knowledge and methods from the field of natural and technological sciences and to see collections as a whole, rather than as single items. The currently exercised approach to the protection of cultural heritage items is consistent with the saying “better prevent than treat,” and all actions, including Integrated Pest Management, create a specific management system for the protection of historical collections.

Biofilms and Disease: A Persistent Threat

Cameron Neil Melton and Gregory G Anderson, Indiana University—Purdue University Indianapolis, Indianapolis, IN, United States

© 2019 Elsevier Inc. All rights reserved.

Introduction

Bacteria are our ever-present neighbors. In fact, most current estimates show that the number of bacteria on and in our body is much greater than the number of human cells in our body (Sender et al., 2016). Though most of our bacterial neighbors are benign, or even beneficial, bacteria continue to kill millions each year across the globe despite continuous spending on the development of new antibiotics. A major factor in the fight against pathogenic bacteria is the formation of these microbes into structured communities known as biofilms. Bacteria living in a biofilm are implicated in most chronic infections and can increase resistance to disinfectants up to 600-fold (Otter et al., 2015) and resistance to antibiotics up to 1000-fold when compared to their free-floating planktonic counterparts (Luppens et al., 2002; Rasmussen and Givskov, 2006; Mah and O'Toole, 2001). The leading sources of nosocomial infections, and the cause of 100,000 deaths per year in the United States, are collectively known as ESKAPE pathogens, consisting of *Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* sp. (Santajit and Indrawattana, 2016). It is no coincidence that each of these dangerous pathogens are known to produce biofilm (Santajit and Indrawattana, 2016).

What Is Biofilm?

Biofilm is a three-dimensional community of bacteria living within a secreted matrix of hydrated excreted extracellular polymeric substances (EPS). Biofilm matrix composition is 97% water by weight with polysaccharides, proteins, lipids, and extracellular DNA making up the remainder (Jamal et al., 2015). The structure and function of the biofilm is adaptable to a vast array of environments and stimuli with heterogeneity in differentiation and function among the bacteria residing within. The secreted matrix of the biofilm creates nutrient and oxygen gradients, resulting in localized differentiation patterns within the biofilm and functional differences between bacteria at the core of the biofilm and bacteria near the outer surfaces (Flemming et al., 2016). Moreover, extracellular DNA (eDNA) binds polysaccharide molecules to form filamentous tubules and pore structures that enable nutrients and water to enter the biofilm and facilitate the movement of cells within the matrix (Flemming et al., 2007). Enzymes embedded within the matrix degrade nutrients and organic compounds, which are then captured by charged polysaccharides for use by the cells residing in the biofilm (Flemming et al., 2016). The biofilm matrix also facilitates chemical signaling between encased bacteria.

Bacteria living within a biofilm are more protected from immune cells and predation by other organisms, more resistant to desiccation and environmental stresses, and more tolerant of antibiotics (Flemming et al., 2016). In many cases, biofilm matrix components bind to antibiotics, which deactivates or slows antibiotic diffusion into the biofilm; the net effect of this action is increased antibiotic resistance (Mah and O'Toole, 2001). Moreover, localized phenotypic changes within the biofilm lead to slower growth, reduced nutrient uptake, and a biofilm-specific phenotype that is recalcitrant to antibiotics (Mah and O'Toole, 2001). These phenotypic changes can be dramatic. In a study looking at the expression of proteins in a mature biofilm of *P. aeruginosa* compared to planktonic *P. aeruginosa*, only 40% of all proteins were expressed similarly in both groups (Sauer et al., 2002). As our understanding of bacterial biofilms has grown, we have learned that phenotypic changes can lead to development of highly-resistant cells deep in the biofilm called persister cells that greatly contribute to the biofilm antimicrobial recalcitrance (Mah and O'Toole, 2001; Gominet et al., 2017; Elgharably et al., 2016; Anderson and O'Toole, 2008).

How Does Biofilm Form?

The formation of a biofilm can be viewed in stages of development and maturation. Thus, it is helpful to think of “biofilm” as a process, rather than a discreet item.

Stage 1: Initial Reversible Attachment

Planktonic or free-floating bacteria come into contact with a surface. Lewis acid-base, electrostatic, and van der Waals interactions guide the initial attachment. A variety of factors influences this process including surface hydrophobicity and charge, pH, and hydrodynamic forces in the microenvironment (Kostakioti et al., 2013). This step is known as “reversible attachment” because detachment often occurs, and it is thought that the microbe is “sampling the surface” (Hoffman et al., 2015). Initial attachment can be mediated by secreted adhesins, flagella, and other surface molecules, depending on the microorganism (Kostakioti et al., 2013). Chemotaxis toward preferred nutrients may also influence the location of initial attachment (Anderson and O'Toole, 2008; Kostakioti et al., 2013).

Stage 2: Irreversible Attachment

In this step, a microbe makes a commitment to the surface and remains bound. Irreversible attachment is most often aided by pili. For example, *Escherichia coli* use type I pili; these are assembled via the chaperone usher pathway (CUP), and the FimH adhesin on the end of the pilus mediates attachment (Anderson et al., 2003). *P. aeruginosa*, however, uses type IV pili with adhesin CupA mediating attachment (Vallet et al., 2001).

Stage 3: Maturation I—Aggregation into Microcolonies

Adhered bacteria secrete EPS to aggregate neighboring bacteria into discrete clusters called microcolonies (Kostakioti et al., 2013). EPS also connects surrounding microcolonies into a thin layer across the adhered surface. This activity makes the surface more conducive to attachment by additional, planktonic bacteria (Huang et al., 2011).

Stage 4: Maturation II—Three-Dimensional Biofilm Formation

As the biofilm continues to grow, eDNA binds to EPS to form a three-dimensional architecture, which gives the biofilm tensile strength and increased rigidity. Many species use quorum sensing signaling between cells to direct phenotypic differentiation in a cell density dependent manner (Flemming et al., 2007; Nealson et al., 1970; Gambello and Iglewski, 1991; Jennings et al., 2015).

Stage 5: Dispersal

The last stage of the biofilm process is the dispersion of some of the cells from the existing community to ensure the survival and propagation of the bacteria. This process can be broken down into two basic modes: active and passive. In an active mode of dispersal, the bacteria respond to community and environmental cues to break down the biofilm matrix and allow the release of cells that can then transit to new locations. Passive dispersal, however, is a result of the environmental forces, such as external organism interaction, fluid shear, or abrasion, dislocating a portion of the biofilm through mechanical disruption (Kaplan, 2010).

Where Do We Find Biofilms?

Biofilms form throughout nature on living and non-living surfaces, both environmental and human-fabricated (Donlan, 2002). Of particular note, microbes often form biofilms during infection (Donlan, 2002). In fact, it is estimated that 80% of all human infections involve a biofilm component (NIH, 2002). We focus on these biofilm infections here, describing biofilms that form within and on tissues and those that form on medical devices.

Tissue-Associated Biofilms

Burn Wounds

Each year, 40,000 individuals in the United States are hospitalized with burns (McDermott et al., 2013). Studies indicate annual expenditures in the United States of \$1.5 billion for burn wound-associated medical costs and \$5 billion in costs related to lost work (McDermott et al., 2013). In a burn, thermal destruction of the skin leaves damaged tissue exposed and prone to infection. Moreover, massive tissue damage results in initial release of an abundance of humoral factors like cytokines, leukotrienes, and prostaglandins that cause an immunosuppressive state in the patient, further increasing the risk of wound colonization and potential systemic infection (Polavarapu et al., 2008). Infection is the leading cause of death in burn wound patients (Polavarapu et al., 2008; Gomez et al., 2009; Ramakrishnan et al., 2016) and biofilm formation is highly associated with mortality (Ramakrishnan et al., 2016). Biofilm growth within the wound bed subsequently promotes a chronic inflammatory state that further impairs wound healing by reducing re-epithelialization and inhibiting the in-growth of granulation tissue (Gurjala et al., 2011). Moreover, burns often lead to formation of eschar, a portion of tough, inelastic, necrotic tissue that forms over the wound. Plasma and wound exudate collect underneath the eschar, putting pressure on the remaining vasculature, impairing circulation to the wound bed and areas distal to the injury (Tiware, 2012). The ischemic wound bed thus created encourages the formation of biofilm (Seth et al., 2012).

Most infections in patients with burns are caused by several major bacteria: *P. aeruginosa*, *S. aureus*, *Streptococcus* sp., and *Acinetobacter*. These bacteria are each associated with biofilm production and antibiotic resistance to one or more agents (Gomez et al., 2009; Ramakrishnan et al., 2016). *P. aeruginosa* is particularly dangerous due to the development of resistance to systemic antibiotics as well as resistance to many topical agents used to prevent or treat burn wound infections.

Treatment for burn wound infections involves an array of modalities. Primary treatment in a severe burn is the debridement of damaged tissue, including coagulated proteins, to create a clean wound bed with tissue that is vascularized; this action promotes wound healing and inhibits infection (Polavarapu et al., 2008). Next, topical antibiotics and/or silver dressings are administered to the wound bed (Metcalfe and Bowler, 2013). Systemic antibiotics are not recommended initially as they are ineffective at preventing wound sepsis due to limited vascularization of damaged tissue and instead promote the development of drug-resistant infections.

Table 1 Selected antibiofilm treatment schemes

Novel treatment approach	Prevention or intervention	How does it work?
Probiotic microorganisms	Prevention	Nonpathogenic microbes out-compete pathogens for nutrients and binding sites (Polavarapu et al., 2008; Delcaru et al., 2016; Soto, 2014)
DNase treatment	Intervention	DNase is used to break down the eDNA that provides structural integrity to a biofilm (Aung et al., 2017; Gnanadhas et al., 2015)
Mucinase treatment	Intervention	Mucinase enzymatically degrades mucoid biofilms (Chandki et al., 2011; Henke and Ratjen, 2007)
Antimicrobial peptides	Both	Antimicrobial peptides can be used prophylactically to prevent microbial growth or can be administered post hoc to attack established biofilms (Sevgi et al., 2013; Wang et al., 2017)
Inorganic metal derivatives (e.g., Silver compounds)	Both	Antimicrobial properties of certain metals can be utilized to prevent infection as well as to treat established infections (Sevgi et al., 2013; Connaughton et al., 2014)
Plant extracts	Both	Extracts inhibit microbial growth and reduce the formation of biofilm (El-Ganiny et al., 2017; Delcaru et al., 2016)
Quorum sensing inhibitors	Both	Inhibitors target the signals that bacteria use to coordinate biofilm formation (Elgharably et al., 2016; Delcaru et al., 2016; Kalanuria et al., 2014)
Diazeniumdiolate compounds	Both	Diazeniumdiolate compounds release NO upon contact with bacteria resulting in biofilm dispersal (Connaughton et al., 2014)

However, such antibiotics are given if sepsis develops (Polavarapu et al., 2008). Novel treatment strategies for biofilm infections of burn wounds include administration of probiotic beneficial microorganisms (Polavarapu et al., 2008), antimicrobial and anti-biofilm peptides (Sevgi et al., 2013; Wang et al., 2017), inorganic metal derivatives, halogens, chitosan, XF porphyrins, phage therapy, and light-mediated therapies (Sevgi et al., 2013) (Table 1).

Keratitis

Keratitis is inflammation of the cornea, usually caused by a bacterial infection, but fungi, protozoa, or viruses can also induce this ailment (Collier et al., 2014; Al-Mujaini et al., 2009). Keratitis is a major cause of corneal opacity and is among the leading causes of blindness (Collier et al., 2014; Al-Mujaini et al., 2009; Bispo et al., 2015). Infection can lead to complete destruction of the cornea in 1–2 days (Al-Mujaini et al., 2009). Contact lens usage is the major risk factor, associated with 56% of bacterial keratitis cases, with poor hygiene and care also precipitating many of the infections (Collier et al., 2014; Zegans et al., 2002). Extended-wear lens users have a much higher incidence of keratitis than daily-wear users: 20.9 per 10,000 people versus 4.1 per 10,000, respectively (Poggio et al., 1989). Prevalence of bacterial keratitis is significantly higher in developing countries (e.g., 11 per 100,000 persons in the United States vs. 799 per 100,000 persons in Nepal) and incidence is rising proportionally as the number of people using contact lenses increases across the world (Al-Mujaini et al., 2009). Keratitis causes nearly 1,000,000 doctor office visits each year resulting in \$175 million in associated medical costs and 250,000 h of clinician time (Collier et al., 2014).

While in the eye, proteins and lipids from the tear fluid adsorb to the surface of the lens creating a conditioning layer on the lens that facilitates the binding of bacteria to the surface (Bispo et al., 2015; Zegans et al., 2002). Bacterial keratitis is primarily caused by three genera, all known biofilm formers: *Staphylococcus*, *Streptococcus*, and *Pseudomonas* (Al-Mujaini et al., 2009). It is thought that biofilm formation on either the abiotic contact lens or the eye itself is what allows the bacteria to persist, thrive, and ultimately infect the eye (Bispo et al., 2015; Zegans et al., 2002). A study in rats observed that contact lenses inoculated with planktonic *P. aeruginosa* caused keratitis in approximately 7 days while contact lenses taken from another infected rat with an adherent *P. aeruginosa* biofilm caused a keratitis in 2 days (Tam et al., 2010). In vivo adaptation of the bacteria, through biofilm formation, resulted in enhanced pathogenesis of the bacteria and reduced the time from inoculation to infection.

There are a variety of ways to prevent or reduce the risk of bacterial keratitis including switching from extended-wear to daily-use contact lenses (Bispo et al., 2015), switching from soft to rigid contact lenses (Al-Mujaini et al., 2009; Bispo et al., 2015), improving hygiene (including hand washing and rubbing of lenses with contact lens solution) (Bispo et al., 2015; Wagner et al., 2014), and more frequent replacement of contact lens cases (Bispo et al., 2015). Between the 1970s and the 1990s, heat disinfection was used to clean contact lens cases. Since then, heat disinfection has become much less prominent as users have switched to contact lens solution (Willcox et al., 2012). Initial studies showed that using a combination of heat and contact lens solution to disinfect the cases significantly decreases viable biofilm bacteria and substantially improves disinfection compared to each method used individually (Willcox et al., 2012). Continued research is needed to develop optimal disinfection procedures to prevent biofilm formation.

Treatment for bacterial keratitis usually involves antibiotic therapy with 4th generation fluoroquinolones, like gatifloxacin or moxifloxacin (Al-Shehri et al., 2009). Several naturally-derived methods have been examined to remove biofilm growth from contact lenses and contact lens cases (Table 1) including using plant extracts from *Calendula officinalis* and *Buddleja salviifolia*, each of which showed nearly complete inhibition of biofilm formation (El-Ganiny et al., 2017). Another proposed approach uses DNase treatment in concert with antibiotic therapy. DNase targets eDNA within the biofilm matrix, thus reducing the structural integrity of the biofilm making the cells within more susceptible to antibiotic therapy (Aung et al., 2017).

Chronic Otitis Media

Chronic otitis media (COM) affects between 65 and 330 million people worldwide, with many under the age of 5 (Mittal et al., 2015). 80% of children less than 3 years old have had at least one incident of otitis media, a portion of which will advance to chronic otitis media (Mittal et al., 2015). Hearing loss is a common complication of COM, which can result in speech and language deficits and problems in school, and hearing loss can be permanent in some cases (Mittal et al., 2015). A study using light and transmission electron microscopy found that 100% of samples taken from patients with COM with exudate showed microbial biofilm formation (Akyildiz et al., 2013). Another study using scanning electron microscopy to analyze tissue samples from patients with COM found that 70% showed biofilm formation on tissues excised during surgery (Kaya et al., 2013). Combined, these studies indicate a pivotal role of biofilms in the pathogenesis of COM.

In cases of COM, biofilm formation is typically located in the middle ear mucosa and less frequently on the mastoid (Kaya et al., 2013; Lampikoski et al., 2012). Often, biofilms form on cholesteatomas, or abnormal skin growths in the ear that can inhibit drainage and function of the ear (Kaya et al., 2013). In COM, infection is most often caused by the biofilm-forming bacteria *P. aeruginosa*, *S. aureus*, and *E. coli* (Mittal et al., 2015; Akyildiz et al., 2013). Despite topical antimicrobial concentrations that far exceed the minimum inhibitory concentrations (MICs) of even the most resistant strains, COM is often recalcitrant to antibiotic therapy (Akyildiz et al., 2013). The interplay of biofilm formation, structural, and anatomic changes, like cholesteatoma formation due to chronic infections, and earwax accumulation may interfere with successful delivery of the antibiotics (Mittal et al., 2015; Akyildiz et al., 2013; Lampikoski et al., 2012).

Treatment for COM often involves aural toilet to remove ear wax, mucus, desquamated epithelial cells, and biofilms through mechanical disruption. This allows for better penetration and more effective delivery of topical antimicrobial agents. The most commonly used antibiotics are aminoglycosides (neomycin, gentamicin, tobramycin) or fluoroquinolones (ciprofloxacin) (Ahmad, 2013). Antibiotics are frequently combined with a cationic detergent like polymyxin B to improve penetration (Miro, 2000). Concurrent use of topical corticosteroids like dexamethasone is also common as the corticosteroids reduce inflammation and the growth of granulation tissue, allowing for greater penetration (Mittal et al., 2015). In children, tympanostomy tubes are often placed to improve drainage and ventilation of the ear canal (Mittal et al., 2015; Vlastarakos et al., 2007). Surgery can be used to correct defects in situations involving patients with abnormal anatomy of the ear (Mittal et al., 2015).

Dental Biofilms

The human oral cavity is home to over 700 different bacterial species (Huang et al., 2011). These bacteria live on many different surfaces in the mouth: from teeth, tongue, and gums, to the oral mucosal surfaces (Huang et al., 2011). Most of these bacteria are harmless and actually serve a beneficial role to the health of the mouth, while other species are connected to infection and invasive disease. It is the competition and complex interaction of healthy microbiota with pathogenic varieties within oral biofilms that can lead to disease (Huang et al., 2011; Hojo et al., 2009; Dewhirst et al., 2010). Beneficial microbes maintain good oral health by excluding more harmful bacteria through several mechanisms (Huang et al., 2011; Hojo et al., 2009). Healthy bacteria are thought to inhibit pathogens by secreting antimicrobial compounds like peroxides or bacteriocins that inhibit nearby pathogens. Additionally, these microorganisms can outcompete pathogens for nutrients and attachment sites (Hojo et al., 2009). Oral dysbiosis, characterized by proportional changes in the ratios of pathogens to non-pathogens in the mouth, has been shown to cause several disease states including periodontitis, tooth decay, tonsillitis, and endodontic infections (Huang et al., 2011; Hojo et al., 2009; Dewhirst et al., 2010). Often, pathogenesis is dictated not by the mere presence of pathogenic bacteria, but rather by the relative abundance of pathogenic bacteria compared to beneficial bacteria, with disease occurring during states of imbalance (Huang et al., 2011). Moreover, the oral microbiota can cause disease states outside of the oral cavity. There are many links between oral health and heart disease, atherosclerosis, and endocarditis (Dewhirst et al., 2010). Thus, good oral health is important for maintaining overall human well-being. Importantly, the persistence of bacterial species within the oral cavity is attributable to biofilm formation. In fact, over 90% of the bacteria in the mouth (both pathogenic and beneficial) live within a mixed-species biofilm on various oral surfaces. A greater understanding of these processes can lead to improved health.

There are interesting correlations between oral disease state and particular types of microorganisms. Cariogenic bacteria, like *Streptococcus mutans*, tend to be acidogenic and Gram-positive. In a healthy, non-cariogenic environment, levels of *S. mutans* are low, whereas cultures from active caries tend to show high levels of *S. mutans* (Chandki et al., 2011). Periopathogenic bacteria, like *Porphyromonas gingivalis*, however, are more likely to stain basophilic and Gram-negative (Chandki et al., 2011). The composition of bacteria within a dental biofilm changes as the biofilm matures. Early colonizers, or pioneers, tend to be *Streptococci* sp., *Neisseria* sp., and *Rothia* sp. (Heller et al., 2016). These bacteria have special adhesins and surface lectins that allow them to bind more readily to the enamel surface of teeth as well as to the layer of surface-bound proteins and lipids that quickly adsorb to the tooth surface when exposed to saliva (Heller et al., 2016). As a dental biofilm matures, additional species accumulate, including *Actinomyces*, *Corynebacterium*, *Fusobacterium*, and *Veillonella* (Heller et al., 2016). *P. gingivalis* is particularly adept at binding to these early colonizers in the supragingival tooth surface and spreading into the subgingival pocket where it can form a nidus of infection that allows the bacteria to persist despite attempts at eradication (Kuboniwa and Lamont, 2010).

Management of oral biofilms traditionally involves regular brushing and flossing of teeth, use of antiseptics and fluoridated mouthwash, and regular cleanings at the dentist that may involve scaling or root planing of the tooth surface to disrupt biofilm

attachment (National Institute of Dental and Craniofacial Research, 2013). In a disease state, topical antibiotics like chlorhexidine and doxycycline may be used either as a rinse or gel (National Institute of Dental and Craniofacial Research, 2013). Systemic antibiotics like penicillin, vancomycin, or erythromycin, as well as enzymatic degradation of dental calculus using mucinase, pancrease, or lactoperoxidase hypothyocyanite, are also used (Chandki et al., 2011). More recently, biofilm-disrupting synthetic peptides have been explored as a novel treatment for unhealthy biofilm growth in the mouth (Table 1) (Wang et al., 2017).

Infective Endocarditis

Infective endocarditis (IE) is a serious condition involving infection of the endocardium that can cause severe damage to the heart and heart valves (Elgharably et al., 2016). As people are living longer, and more cardiac devices and prosthetic valves are being implanted, the rate of IE has increased significantly in the last 30 years (Forestier et al., 2016). Precipitating the development IE, bacteria in the bloodstream bind to damaged cardiac tissues and create biofilm communities called vegetations (Hoen and Duval, 2013). These bacteria can come from the oral cavity (as discussed above), from infections at distal locations, and from contaminated implanted medical devices (we discuss device-related biofilm infections below), among other sources. *Streptococci*, *Staphylococci*, or *Enterococci* cause 80% of IE cases, and, importantly, each of these genera are known biofilm-formers (Elgharably et al., 2016). Studies looking at bacterial isolates from IE lesions showed that IE isolates were significantly more likely to produce biofilm than non-pathological isolates of the same species, indicating an important role for the biofilm process in cardiac infection (Nallapareddy et al., 2006). Attachment to the endocardium is mediated by fibronectin and polysaccharides (Elgharably et al., 2016). Often, biofilm is adhered to fibrin-platelet plugs that give structure to vegetations (Elgharably et al., 2016; Hoen and Duval, 2013). Cardiac vegetations can mechanically interfere with valve function. Additionally, parts of the vegetation can break off and cause infections elsewhere in the body or block the flow of blood, leading to systemic infections, stroke, heart failure, or meningitis (Elgharably et al., 2016; Hoen and Duval, 2013). IE is thus a very dangerous condition with a 20% mortality rate in year one and 40% over five years (Hoen and Duval, 2013).

Current treatments for IE consist of intravenous antibiotics. However, IE is often recalcitrant to antibiotics likely due to phenotypic changes of the bacteria within the biofilm and creation of highly-resistant persister cells deep in the biofilm (Elgharably et al., 2016). Treatment failure due to antibiotic resistance often necessitates surgical removal of infected tissue and/or prosthetic valves or other cardiac implants, as well as radical debridement of the area, imposing significant risks and costs on the patient and medical system (Elgharably et al., 2016; Hoen and Duval, 2013). New strategies to treat IE include antibiofilm peptides and quorum sensing inhibitors, among others (Table 1) (Elgharably et al., 2016; Reffuveille et al., 2014).

Urinary Tract Infections

Urinary tract infections (UTIs) affect 150 million people across the world annually, necessitating 12–14 million medical visits in the United States each year (Flores-Mireles et al., 2015). As the reason for nearly 1% of all doctor visits and costing \$3.5 billion per year in the United States alone, UTIs represent a major public health issue (Flores-Mireles et al., 2015; Stamm and Norrby, 2001). Bacterial biofilms are thought to be responsible for recurrent and persistent infections, particularly nosocomial infections and catheter-associated UTIs (CAUTI; discussed further below) (Delcaru et al., 2016). Over a quarter of patients who develop a UTI will suffer recurrences (Stamm and Norrby, 2001). Moreover, many suffer additional complications, including kidney damage, pyelonephritis with sepsis, and pre-term birth in pregnant women (Flores-Mireles et al., 2015; Stamm and Norrby, 2001). Long-term antibiotic use to treat persistent UTI can result in *Clostridium difficile* infections, such as antibiotic-associated diarrhea and pseudomembranous colitis (Flores-Mireles et al., 2015).

Most UTIs (80%) are caused by *E. coli*, particularly uropathogenic *E. coli* (UPEC) strains (Anderson et al., 2003, 2004; Flores-Mireles et al., 2015; Delcaru et al., 2016). *Proteus mirabilis*, *K. pneumoniae*, *P. aeruginosa*, *Enterococcus* sp., *Enterobacter* sp., group B *Streptococcus*, and *Staphylococcus saprophyticus* are also found as causative agents, albeit less frequently (Anderson et al., 2003). Bacteria use a variety of strategies to colonize the urinary tract, including adhesin-displaying pili to mediate attachment to epithelial cells (Anderson et al., 2004). A study of *E. coli* strains collected from patients experiencing relapse and recurrence of UTI showed that 74% of bacterial isolates from relapsing UTI formed biofilms in vitro compared with 42% from other recurrent infections, indicating an important role for biofilm in the pathogenesis of UTIs (Soto et al., 2006). Moreover, in addition to extracellular biofilms on urinary catheters, it has been shown that UPEC forms intracellular biofilms in the epithelium of the bladder, which may be a key persistence mechanism that enables their recalcitrance to treatment in some patients (Anderson et al., 2003).

Treatment for UTI typically involves oral antibiotics, however many cases recur despite antibiotic treatment (Delcaru et al., 2016). Home treatment for UTIs frequently entails cranberry juice and cranberry juice extract capsules. Cranberries contain proanthocyanidins and polyphenols which have shown antibiofilm properties in vitro (Liska et al., 2016). Cranberry-based treatments reduce the risk of symptomatic, recurrent UTIs, however the exact mechanism of activity remains unclear (Wang et al., 2012). There are a variety of novel treatment strategies for difficult-to-treat UTIs (Table 1) including plant extracts like *Rosmarinus officinalis*, *Salvia officinalis*, and *Mentha piperita* which can inhibit a biofilm lifestyle while preventing antimicrobial resistance (Delcaru et al., 2016). Other approaches include using nanoparticles to penetrate biofilms, using biofilm-targeting bacteriophages, and quorum sensing inhibitors to target the signals that lead to biofilm production (Delcaru et al., 2016).

Cystic Fibrosis Lung Infection

Cystic fibrosis (CF) is a disease caused by a mutation in the cystic fibrosis transmembrane conductance regulator (CFTR) protein, which forms chloride channels. This mutation causes problems throughout the body including gastrointestinal disorders, fertility problems in males, and most notably progressive lung function decline (O'Sullivan and Freedman, 2009). The decline in lung function is due to increased viscosity of lung secretions which creates a niche within the lungs for pathogens to thrive (O'Sullivan and Freedman, 2009). CF is the most common inherited lethal disorder among people with European descent, affecting 1:2500–1:3000 births in this population (O'Sullivan and Freedman, 2009; Scotet et al., 2012). Life expectancy for people with CF has nearly doubled over the last two decades due to advances in medication, physical therapy modalities, and improved understanding of the disease (O'Sullivan and Freedman, 2009; Scotet et al., 2012). However, lung infections, particularly involving biofilm-forming pathogens, remain the leading cause of death among people living with CF (O'Sullivan and Freedman, 2009).

In the CF lung, there are a variety of environmental cues that promote biofilm infections, including: thickened lung secretions leading to hypoxic conditions within pooling mucus, reduced ciliary clearance, chronic inflammatory immune response, and high antibiotic levels (O'Sullivan and Freedman, 2009; Hoiby et al., 2017; Anderson et al., 2008). Immune response is mediated by polymorphonuclear leukocytes, which release their DNA when they die, further contributing to the increased viscosity of lung secretions and providing additional structure to biofilm formations in the lungs (O'Sullivan and Freedman, 2009; Hoiby et al., 2017). High antibiotic levels have also been shown to influence biofilm formation in vitro (Anderson et al., 2008). Infections are most commonly caused by *P. aeruginosa*, *S. aureus*, *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, and atypical mycobacterium (O'Sullivan and Freedman, 2009; Hoiby et al., 2017). *P. aeruginosa* is one of the most concerning CF lung pathogens, and patients that successfully avoid *P. aeruginosa* infections tend to have a significantly increased life expectancy (O'Sullivan and Freedman, 2009; Hoiby et al., 2010). 98% of young children with CF show signs of infection with this microorganism (Burns et al., 2001). *P. aeruginosa* is adept at forming biofilms within the CF lung, which makes the infection dramatically more difficult to treat with antibiotic therapy. Indeed, once a chronic *P. aeruginosa* biofilm infection has taken hold, it is nearly impossible to eradicate (Hoiby et al., 2010).

Treatment and prevention of CF-related infections, including biofilms, typically involve physical therapy to improve airway clearance, bronchodilators, mucolytic therapy such as dornase alfa, hypertonic saline solution to hydrate lung secretions, molecules to potentiate or correct CFTR function (such as Ivacaftor), and antibiotic therapy (O'Sullivan and Freedman, 2009; Condren and Bradshaw, 2013; Henke and Ratjen, 2007; Cutting, 2015; Claudius et al., 2015). Novel treatment strategies for CF-related biofilms (Table 1) include L-methionine in conjunction with antibiotics; L-methionine upregulates DNase activity, which degrades the structural integrity of the biofilm by attacking eDNA (Gnanadhas et al., 2015). Another new treatment approach involves using nitric oxide to disrupt biofilms by increased phosphodiesterase activity, resulting in a decrease in the biofilm regulatory molecule cyclic-di-GMP (Howlin et al., 2017). However, one of the most effective ways to conquer *P. aeruginosa* biofilms is to prevent it in the first place. Early, aggressive antibiotic therapy during the initial acute colonization of the lungs, when the bacteria are far more susceptible to antibiotics, can prevent over 80% of chronic *P. aeruginosa* infections (Hoiby et al., 2010).

Implant- or Device-Associated Biofilms

Prosthetics

As the population ages in the developed world, the number of total joint arthroplasties (TJA) is greatly increasing (McConoughey et al., 2014; Maradit Kremers et al., 2015). Over 1 million TJA procedures are performed each year in the United States (Maradit Kremers et al., 2015). Among patients who receive TJA, infection is a major cause of surgical revision (McConoughey et al., 2014; Pandey et al., 2000). Infection of a prosthetic joint is estimated to cost \$50,000 per incident (Connaughton et al., 2014).

Infection of an artificial joint stems from several sources: microbes that were on the surface of the implant, microbes introduced by the surgical team or surgical environment, and through hematogenous spread. The most common bacteria involved in orthopedic infections include: *Staphylococcus* sp., *Enterococcus* sp., *Klebsiella* sp., *Pseudomonas* sp., and *Acinetobacter* sp. (Pandey et al., 2000; Fernandes and Dias, 2013). Biofilm formation on the surface of the implant makes the constituent bacteria more resistant to sterilization pre-implantation and much more resistant to antibiotic treatment in vivo. Moreover, the lack of vascularization of the tissues at the surface of the implant dramatically reduces antimicrobial penetration into the biofilm (Pandey et al., 2000; Fernandes and Dias, 2013; Lamagni et al., 2015).

Treatment for orthopedic infections primarily involves antibiotic therapy. However, the difficulty in treating biofilm infections in an avascular environment often necessitates surgical revision to remove the infected implant (Lamagni et al., 2015). For this reason, prevention of infection is most effective. Improved aseptic surgical techniques have greatly improved outcomes (Fernandes and Dias, 2013), and several novel techniques have been explored to further reduce the risk of biofilm infections in TJA. Changes to the implant surface chemistry or pretreatment with antimicrobial substances can inhibit colonization of the surface. A variety of surface treatments are being pursued (Table 1), including a polyethylene oxide coating, silver or copper ions, metal nanoparticles or nanotubules, impregnation of the implant with antimicrobial peptides, diazeniumdiolate coatings that release nitric oxide, and altering the implant to generate a hydrophilic surface charge (Connaughton et al., 2014).

Central Venous Catheters

Central venous catheters (CVCs), also known as central line catheters, are used to deliver medications, blood products, or nutrition directly into the bloodstream of chronically ill or critically ill patients over a long period of time. CVCs can be kept in place longer than standard intravenous catheters, so they are ideal for patients receiving treatment modalities requiring long-term intravenous therapy. However, CVCs also form a portal from the environment directly to the bloodstream and are associated with a significant risk of bloodstream infection (Yousif et al., 2015). CVCs are the leading cause of bacteremia among patients who have been hospitalized (Gahlot et al., 2014). There are between 250,000 and 500,000 central line-associated bloodstream infections (CLABSIs) each year in the United States (Yousif et al., 2015; Maki et al., 2006). These infections increase length of hospitalization by 10–20 days and result in up to \$2.5 billion in medical costs in the United States each year (Yousif et al., 2015; Shah et al., 2013). Importantly, CLABSIs increase mortality of hospitalized patients, to 15%–25% (Maki et al., 2006).

Most CLABSIs are caused by bacteria from the patient's skin, although contamination can occur from the hub site, hematogenous spread from another infection site, or, rarely, from administering contaminated products through the catheter (Gominet et al., 2017; Gahlot et al., 2014; Shah et al., 2013). The organisms most likely to cause infections are *Staphylococci*, Gram-negative bacilli, enterococci, and yeast, with *S. aureus* the most prevalent etiological agent (Shah et al., 2013). Biofilm formation on the catheter can begin less than 24 h after insertion and protects the bacteria from host immune attack and from antibiotic therapy (Gominet et al., 2017). As the biofilm matures, the dispersal process begins, causing bacteremia and sepsis as pathogens are shed from the community directly into the bloodstream. Many bacteria remain behind, though, including durable persister bacteria, to maintain the localized infection (Gominet et al., 2017; Shah et al., 2013).

Strategies to combat CLABSIs begin with prevention of the underlying contamination, with hygiene and maximal sterile barrier technique playing a very important role (Gominet et al., 2017). Most infections are treated with intravenous antibiotics, often through the contaminated catheter if the catheter is still in-place (Shah et al., 2013). These antibiotic lock solutions are a good strategy to salvage necessary catheters that have been contaminated. The process involves filling the catheter with highly-concentrated antibiotic solutions; the high concentration is necessary to attack biofilm-state cells (Gominet et al., 2017). However, despite attempts to eradicate already growing biofilms on catheters, removal of the catheter is still considered the most effective way to respond to CLABSIs due to the recalcitrance to any eradication efforts (Gominet et al., 2017). Other ideas to prevent CLABSIs include impregnating catheters with silver compounds, antimicrobial drugs, or antimicrobial peptides to inhibit initial biofilm formation (Table 1) (Gominet et al., 2017).

Urinary Catheters

Catheter-associated urinary tract infections (CAUTIs) are the most common nosocomial infections (Trautner, 2010). CAUTI is associated with risk of acute renal inflammation and is one of the largest drivers of antibiotic use (Trautner and Darouiche, 2004). Hospital wards that operate without catheters showed a 90% drop in antibiotic usage (Trautner and Darouiche, 2004). Furthermore, antibiotics are often ineffective in treating most CAUTIs as many infections are caused by biofilms growing on the lumen of the catheter itself, which lacks any vascular perfusion that would normally deliver antibiotics to an infection site (Trautner, 2010; Trautner and Darouiche, 2004). Catheterization, by definition, undermines the best defenses against infection by forming an open portal through which bacteria can enter the urinary tract (Hamill et al., 2007). Moreover, catheterization causes damage to adjacent epithelial tissues, which can enhance susceptibility to additional infections (Trautner and Darouiche, 2004). It is estimated that the cost of CAUTIs in the United States and Europe is nearly \$3 billion per year (Hamill et al., 2007). Moreover, catheterization is strongly correlated with increased mortality (Trautner and Darouiche, 2004; Hamill et al., 2007).

CAUTIs are most commonly caused by Gram-negative species, with *E. coli* the most common (causing nearly 80% of all UTIs) (Trautner and Darouiche, 2004; Hamill et al., 2007; Mobley et al., 2009), followed by *Proteus mirabilis*, *P. aeruginosa*, and *K. pneumoniae* (Hamill et al., 2007). Gram-positive bacteria like *Staphylococcus epidermidis* and *Enterococcus faecalis* are also known to cause infections (Hamill et al., 2007). Urine is an excellent medium for *E. coli* and it enhances the growth of bacteria on catheters as the bacteria are provided a continuous supply of fresh urine (Mobley et al., 2009). Moreover, UPEC strains have developed an array of virulence factors that facilitate UTI progression. The genome for UPEC strains is up to 1 Mb larger than other *E. coli* strains (Lloyd et al., 2007), and much of this additional genome encodes for attachment factors, host defense protection mechanisms, several antimicrobial resistance elements, iron-capture mechanisms, and more that help the cells adapt to the unique environment of the urinary tract (Anderson et al., 2004; Lloyd et al., 2007).

There are a variety of strategies to combat CAUTIs, particularly biofilm infections caused by indwelling catheters. The primary method is prevention (Trautner, 2010; Trautner and Darouiche, 2004). Reducing the rate and duration of catheterization can dramatically reduce the number of infections (Trautner and Darouiche, 2004). Regular changing the catheter and moving toward a closed system with a fused tube connected to the collection bag can help reduce the risk of infection (Trautner, 2010; Hamill et al., 2007). Going further, impregnating catheters with antibiotics, silver compounds, bacteriophages, nitric oxide, or urease-inhibitors has the potential to reduce the risk of colonization of the catheter itself (Delcaru et al., 2016). Other treatments being explored include disrupting quorum sensing, using iron-scavenging materials, and even bacterial interference through non-pathogenic strains of *E. coli* that act as probiotic strains that can out-compete pathogenic strains for nutrients and attachment sites (Table 1) (Delcaru et al., 2016; Soto, 2014).

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is pneumonia that forms in a patient who has been mechanically ventilated for more than 48 h. The chance of developing VAP increases the longer a patient is on a ventilator (Gadani et al., 2010). VAP is also associated with increased morbidity and mortality, longer hospital stays, and an increased burden on medical systems (Gadani et al., 2010; De Souza et al., 2014), costing an estimated \$10,000 to \$25,000 per incident (Fernandez et al., 2012). Mortality associated with VAP is estimated between 33% and 50% (Kalanuria et al., 2014). Recent research has pointed to biofilm growth on the endotracheal tube (ETT) as the most important precipitating factor in the development of VAP and a main target of strategies to prevent it (Fernandez et al., 2012; Gil-Perotin et al., 2012).

The main causative agents of VAP include *P. aeruginosa*, *K. pneumoniae*, *Acinetobacter* sp., and *S. aureus*, with *Streptococci* and *Haemophilus influenzae* occasionally implicated in early-onset VAP. The fungus *Candida albicans* is also frequently found to be involved in VAP (Khilnani and Jain, 2013). Among these, *P. aeruginosa* and *S. aureus* are the most common infecting pathogens, with *P. aeruginosa* tied to an increased risk of mortality (Kalanuria et al., 2014). Universally, biofilm forms on the ETT (De Souza et al., 2014). Lung infection occurs as increased tracheal secretions allow for microaspiration of dispersed bacteria from the ETT to colonize the lower airways (De Souza et al., 2014; Kalanuria et al., 2014).

Treatment for VAP involves intravenous or inhaled antibiotics (Kalanuria et al., 2014; Gil-Perotin et al., 2012). Some novel strategies for preventing in VAP include impregnating ETTs with antimicrobials like natural antibiotics or silver compounds, iron-scavenging materials, and quorum sensing inhibitors (Table 1) (Kalanuria et al., 2014). Other approaches focus on preventing microaspiration by addressing cuff pressure, material, and shape (Fernandez et al., 2012). Another potentially promising therapy involves photodynamic treatment in combination with photosensitizers to eliminate 99.9% of biofilm growing on ETTs (Biel et al., 2011).

Conclusion

The nature of our interactions with bacteria is complex and the roles bacteria play in our lives range from necessary and beneficial to pathogenic and deadly. With the emergence of bacteria that are highly-resistant to all antibiotics, we may be entering a post-antibiotic era (Chen et al., 2017; McGann et al., 2016). In this context, understanding the mechanisms that bacteria use to evade eradication is of vital importance. Indeed, years of research has already revealed new targets for antibiofilm therapy, leading to novel treatment strategies that could be effective against a wide range of biofilm infections (Table 1). Considering the integral role of biofilms in numerous human infections, understanding and combatting biofilm has the potential to save millions of lives across the globe.

Introduction

Definitions

In line with the current literature and regulations, biological warfare (BW, biowar, germ war) can be defined as the intentional use of harmful biological organisms such as bacteria, viruses and fungi or their products (toxins) in warfare to cause damage on humans, animals or plants. The warfare is legally the conflict between states, that is, attacks by nonstate actors would have to be considered as bio-terrorism. Biological warfare was never considered as stand-alone action, but as embedded into a wider range of military activities.

Theoretically any harmful biological agent that could be released with bad intentions is a biological weapon, but from a legal, political and military perspective, bioweapons are those biological agents which potentially could cause mass casualties as Weapons of Mass Destruction (WMD). The security institutions handle bioweapons in the CBRN (chemical, biological, radiological and nuclear) threat complex. The targeted attack on single individuals with harmful organisms or toxins would be a matter of crime or-if politically motivated-of bioterrorism, but not an act of biological warfare.

In contrast to other WMDs, with the exception of the extinct smallpox virus, all agents and their infections occur naturally as well. The agents themselves can thus not be forbidden and the research on them is medically needed, as demonstrated by the recurrent Ebola outbreaks.

Brief History

The history can be divided into two phases: In ancient times and medieval age, people were already aware that some diseases could be spread by the people who had the diseases. This resulted in defensive measures (separation of people with Leprosy, quarantine of ships to prevent Black Death pandemics), but occasionally also in offensive measures, for example, throwing sick bodies into areas controlled by the enemy by catapults. In the 18th and 19th century, attempts by White Americans to intentionally infect Indians with smallpox were reported, but these incidents are still debated.

The second phase started with the understanding of the existence of infectious agents at the beginning of the 20th century. During World War I, Germany was accused for the use of glanders (*Burkholderia mallei*) and anthrax (*Bacillus anthracis*) against animals. World War I finally led to the Geneva Protocol of 1925, which banned the use of biological weapons for the first time. In World War II, there were reports of bio-attacks in the Sino-Japanese War based on the research of Japan's Unit 731 by using ceramic bombs with infected fleas to spread bubonic plague. During the Cold War, leading powers like the United States (locations in Fort Detrick in Maryland, the Dugway Proving Ground test area etc.), United Kingdom (Porton Down) and the Soviet Union (multiple locations) continued research on biological weapons. Several experiments with open air release in the late 1940s and 1950s for example, with anthrax spores and exposure of volunteers to the Q-fever agent *Coxiella burnetii* took place.

The United States and the Soviet Union supported the United Nations Biological and Toxin Weapons Convention from 1972 which made the development, production and stockpiling of biological and toxin weapons illegal. By defected experts, it became public that the Soviet Union continued to produce bioweapons in their Biopreparat organization, which apparently collapsed with the Soviet Union in the early 1990s.

Current Situation

There are concerns on continued bioweapon research. Since 2015, the Russian Military Scientific Committee of the Armed Forces affiliated to the National Defense Management Center (NDMC) runs Science Squadrons with staff from leading universities; their mostly classified research activities include biotechnology. However, evidence for bioweapon research is missing.

Russia expressed also concerns triggered by the targeted collection of synovial fluid/RNA samples from Russians by the US Air and Training Command 2017, but US denied bad intentions. Medically relevant genetic differences between ethnics exist (e.g., tolerance against paracetamol/acetaminophen), but no genetic variance allowing a bio-attack on a certain population is known yet, that is, a so-called ethnic bomb remains hypothetical.

Smallpox may still be stockpiled as bioweapon, so US military personnel on the Korean peninsula and staff of the US Central Command must be vaccinated with smallpox vaccine.

[☆]Change History: December 2018. KP Saalbach has made minor changes to the text and references.

This article is an update of J.A. Poupard, L.A. Miller, Biological Warfare, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 1–13.

China expressed concerns about the ongoing gain of function (GoF) research which tries to increase contagiousity and damage to the infected organism by targeted virus mutations. In 2016, a researcher re-created the extinct horse pox virus by synthetic DNA. The dual use research of concern (DURC) is also an issue as the advances in genome editing (CRISPR/CAS9-technology) significantly reduce the hurdles for genetic modifications and may enhance biohacking activities.

Biosecurity Framework

The most important global regulation is the United Nations Biological and Toxin Weapons Convention from 1972 which prohibited the development, production and stockpiling of biological and toxin weapons. The use of biological weapons by nation states was already prohibited by the Geneva protocol from 1925. In response to 9/11 and to the subsequent anthrax incidents, the institutional framework was expanded to cover all aspects of biological warfare, biodefense and biothreats. Table 1 shows the biosecurity architecture of the United States in 2018.

The Biological Weapons and Anti-Terrorist Act from 1989 clarifies the penalties for those, who unlawfully try to gain or to work with bioweapons or try to gain too large portions of the smallpox genome sequence.

For military prevention, the United States set up in 1998 the Military Vaccination (MILVAX) Programs in particular for smallpox and anthrax, but also general vaccinations (e.g., influenza) under the direction of the Military Vaccine Agency. The program provides consultation services, education, safety surveillance and research support.

Table 1 Biosecurity architecture of the United States

<i>Sector</i>	<i>Institution</i>	<i>Responsibilities include</i>
Government (Executive Office of the President of the United States) ^a	Biological Defense Research and Development Subcommittee (BDRD) of the National Science and Technology Council (NTSC) managed by the Office of Science and Technology Policy (OSTP)	NTSC coordinates the Science and Technology Council, the BDRD provides an interagency forum for coordination and collaboration on biodefense and biothreats matters
Civil Sector US Department of Health and Human Services (HHS) ^{b,c}	Center of Disease Control (CDC) and Prevention	The CDC runs the Select Agents Program to protect the public from dangerous organisms and toxins. The Biosafety Level 4 laboratories are the official US repository for smallpox
	National Institute of Health (NIH) with subordinate National Biosecurity Advisory Board (NSABB)	Formulates Policies for Biosafety and Recombinant DNA; Biosecurity with Dual Use Research of Concern (DURC) and gain of function (GoF) research and Emerging Biotechnologies
	Biomedical Advanced Research and Development Authority (BARDA)	Project BioShield for funding of research, development and stockpiling of vaccines and treatments in case of CBNR emergencies BARDA procures materials for the Strategic National Stockpile (e.g., Anthrax vaccine)
	Public Health Emergency Medical Countermeasures Enterprise (PHEMCE) Food and Drug Administration (FDA)	Interagency cooperation to advise secretary of HHS with respect to Medical Countermeasures (MCM) Regulation and approval of MCM, FDA is also responsible for food security
US Department of Agriculture (USDA) ^c	Environmental Protection Agency (EPA)	Biological incident response (characterization, decontamination, and waste management), water infrastructure protection. USDA is overall responsible for plant and animal protection
Intelligence (Department of Homeland Security DHS) ^c	National Biodefense Analysis and Countermeasures Center (NBACC)	NBACC is a research laboratory at Fort Detrick for threat assessments in the National Biological Threat Characterization Center (NBTHC) and bioforensics in the National Bioforensic Analysis Center (NBFA). The DHS provides Material Threat and Bioterrorism Risk Assessments (MTAs/BTRAs), manages the early warning program BioWatch and runs the National Biosurveillance Integration Center (NBIC) for interagency cooperation
Military (Department of Defense DoD) ^c	Defense Threat Reduction Agency (DTRA) with Joint Science and Technology Office for Chemical and Biological Defense	Coordinates research by US Army Medical Research Institute of Infectious Diseases (USAMRIID) as part of the US Army Medical Research and material command (USARMRC) USAMRIID is the primary facility for defensive research against biological warfare with a top-level (Biosafety Level 4) laboratory. Research is also done by further actors

^cGAO (2017). Biodefense - federal efforts to develop biological threat awareness. Report GAO-18-155, condensed from pp. 9–12 and Appendix II, pp. 46–50.

After 9/11 and the subsequent anthrax incidents, the US released the Patriot Act and the Public Health Security and Bioterrorism Preparedness and Response Act 2002 which was the basis for the Select Agent Rules last finalized in 2005. As shown in Table 1, new institutions were the NBACC in 2002, the NSABB in 2004 and the BARDA, which was established in 2006 through the Pandemic and All-Hazards Preparedness Act. There is an ongoing biosecurity debate whether a centralization of organizations and budgets may improve effectiveness. The National Biodefense Strategy of 2018 introduced a Biodefense Steering Committee chaired by the HHS and proposed a coordinated information collection, distribution and analysis.

In 2002, the European Medicines Agency EMEA (meanwhile EMA) released guidelines and recommendations for bioterrorism. The seven EU laboratories with the highest Biosecurity-Level (BSL) P4 were linked with each other to ensure information exchange, exercises, trainings and education. Already in 2003, the European Commission introduced strict surveillance rules for *Bacillus anthracis*, *Francisella tularensis*, *Coxiella burnetii* (Q-Fever) and smallpox and added these rules to an EU list of critical infectious agents.

The prohibition of offensive BW does not forbid defense BW measures, so the North Atlantic Treaty Organization (NATO) still conducts BW Preparedness Exercises for example, with inactivated anthrax for defensive purposes.

Bioweapons

Practical Aspects

In biosecurity practice, bioweapons are those agents which can cause harm to a larger number of people as WMD.

Viruses dependent on blood transfer cannot be easily spread, so only agents which can be spread via the air are used as bioweapons. Too large particles would fall down to earth where many agents degrade quickly, with the exception of anthrax spores that could rest for years. So only those agents with a few microns length are of military relevance. The delivery can be done by aerosols or more targeted by missiles, but the agents need to survive the explosion/release in the target region. Mass infection requires mass production, but scale-up of such agents is complex and significantly increases the risk for detection and of accidents. Cultivation (feeding, cleaning, temperature, storage, optimization of pH values and electrolyte balance etc.) requires significant experience. Sometimes, the agents have to undergo special preparatory steps, for example, a microscopic sealing procedure of anthrax particles to improve inhalation. Altogether, bioweapon production and use is a high-tech matter and with the current state of the art, large-scale bioterrorist attacks are unlikely without financial and technical support of nation states.

Genetic engineering did not lead to new superorganisms so far. General strategies are mutations, that is, change of genetic code resulting in altered protein products; insertion of new genes into the set of genes of an organism (genome), resulting in additional proteins and functions and finally deletion of genes, resulting in loss of functions of the organism, for example, to make viruses less harmful (attenuation) and to utilize them for vaccines. Insertions and mutations could create an energetic burden and may change structure and function; these obstacles prevented the creation of superorganisms and new bioweapons.

Classification

Introduction

Current bioweapons can be differentiated into bacteria, viruses and toxins. The Center for Disease Control and Prevention (CDC) has released an internationally recognized Bioweapon Classification with the three categories A (highest risk; easily spread or transmitted with high death rates and major public impact such as smallpox and anthrax), B (high risk; moderately easy to spread, moderate illness rates and low death rates such as *Coxiella burnetii* (Q-fever) and C (emerging pathogens with future risk).

Medical Countermeasures (MCM) are preventive, that is, avoiding contact to infectious agents and vaccination, therapeutic, that is, treating the infectious agent directly, like antibiotics for bacteria, antivirals for viruses and antitoxins for toxins or supportive/symptomatic, that is, treating symptoms like shock, fever, myalgia, headache, nausea etc.

Conventional bioweapons

Considering the overall research intensity and the real military production and stockpiling in the past, the primary conventional bioweapons are the smallpox virus, the bacteria *Bacillus anthracis* (Anthrax), *Francisella tularensis* (Tularemia) and *Yersinia pestis* (Plague), the bacteria-like *Coxiella burnetii* (Q-fever) and the toxins Staphylococcal Enterotoxin B (SEB) and Botulinum toxin (BT). While Ebola has no biowarfare history, it is considered as a potentially fatal biothreat (with the risk of spreading by air travelers after an outbreak) and part of the regulatory framework.

Viruses

Smallpox (*Variola major*) After oral infection, a massive viral replication takes place in lymphatic tissues with subsequent swelling of lymph nodes, then it returns to body surfaces (mucosa and skin with multiple lesions) allowing infection of others. Smallpox virus was officially declared extinct in 1980 after an intense global vaccination and surveillance campaign. The vaccination against smallpox (which historically was the first vaccination) was then stopped due to side effects like brain inflammation (encephalitis) or heart inflammation (perimyocarditis).

Officially, smallpox viruses are safely stored at only two locations in the United States and Russia, the Center for Disease Control and Prevention (CDC) in Atlanta and the Center of Virology and Biotechnology (VECTOR) in Koltsovo, but for example, in 2014 the United States National Institute of Health (NIH) found forgotten frozen poxviruses in their own archive.

The key biodefense strategy is vaccination. In July 2018, the US FDA approved the first smallpox-specific antiviral drug tecovirimat, which blocks the enveloping protein p37, after efficacy tests with rabbit pox and monkey pox in animals and safety tests in healthy humans. Only very limited data are available for the antivirals cidofovir and ribavirin. Since decades, a milder (attenuated) smallpox variant, the vaccinia virus (VV) exists, which is further developed by cultivation and mutation to make it milder while keeping its efficacy (causing immunity). To reduce side effects, a new variant which lost the ability to replicate, the Modified Ankara Strain (MAV), was recently cultivated. Now a synthetic viral platform for pox vaccines is developed and the virus researcher Evans re-created the extinct horse pox virus by synthetic DNA in 2016, but the combination of DNA fragments was complex and required for example, the involvement of a helper virus system.

Viral hemorrhagic fevers (VHF)/Ebola Viral hemorrhagic fevers (VHF) including Ebola Virus, Marburg Virus and others cause severe inner bleedings (e.g., as spontaneous nose bleeding). Due to recurrent outbreaks, the World Health Organization (WHO) and others have gained a lot of experience with infection control. Treatments of Ebola with the antiviral drug ribavirin and the chimeric antibody combination ZMapp as well as vaccinations remain experimental.

Bacteria

Anthrax (*Bacillus anthracis*) can form spores which after inhalation get in contact with immune cells. Certain anthrax proteins protect the spores against destruction and cause hyperinflammation, an overactive immune system with shock-like symptoms. In nature, skin infections are more common, while bioweapons aim on inhalation. Vaccination and antibiotics such as ciprofloxacin are used.

Francisella tularensis causes Tularaemia, a highly infectious diseases which can be inhaled or transferred by contact with wild animals leading to severe fever and sepsis symptoms. Antibiotics such as streptomycin and gentamicin are used.

Yersinia pestis causes plague, typically transmitted by infected flea. The infection causes a painful lymph node swelling, known as buboes, then septic reactions follow, appearing as Black Death. Antibiotics like streptomycin are used, limited data exist for other drugs.

Q-fever is caused with *Coxiella burnetii* which may lead to pneumonia (lung infection), but also to chronic heart valve infections. Treatment is done with antibiotics of tetracycline type, gyrase blockers and others.

Toxins

Staphylococcal enterotoxin B (SEB) is a bacterial toxin released by *Staphylococcus aureus*. It overstimulates the immune system as superantigen and causes severe gastrointestinal symptoms, dizziness, vomiting, vertigo etc. It naturally occurs as food and water intoxication. Treatment is symptomatic only.

Botulinum toxin (BT) is a protein released by bacterium *Clostridium botulinum* which irreversibly blocks cholinergic synapses, causing neuromuscular blockade. Equine botulinum antitoxin is effective, if timely given.

Biodefense Considerations

Harmful biologic agents can suppress, confuse or overstimulate the immune system, which can deteriorate infections or lead to shock-like symptoms.

Some agents are suppressing the immune system by blocking certain molecules, for example, many viruses block the immune defense by interferon blockade. Some viruses like the Spanish Flu influenza virus can enhance secondary (on top) infections (infections on top with bacteria which increase morbidity and mortality, so an antibiotic treatment can sometimes be indicated influenza cases).

Bacteria may overstimulate the immune system, by circulation in blood or too many bacterial fragments after destruction by immune system or by releasing superantigens which lead to a diffuse and untargeted massive activation of the immune system. Viruses may also cause overstimulation for various reasons.

Meanwhile, it was found that the altered immune hormone (cytokine) communication plays a role for morbidity and mortality by shock-like and septic symptoms. This was shown for many harmful agents like smallpox (by virus homologs of cytokines, called virokines), anthrax, Ebola and SEB (all causing massive cytokine release), but may also be important for weaponization of viruses by GoF Research.

So the understanding and the correction/suppression of cytokine excesses is a relevant biodefense strategy in case of new GoF-based bioweapons and for classical biological weapons like anthrax, smallpox, Ebola and SEB.

Attribution of Biological Attacks

The nature of an attack as well as the attacker identification is a matter of bioforensic attribution. There are indicators for an intentional use (compared to natural outbreak), for example, sudden outbreak of uncommon diseases with high morbidity and mortality such as a massive zoonosis outbreak only in humans.

The characteristic structure of bioweapon facilities may identify potential attackers. The order and shipment of research materials, bioreactors, feeding materials etc. can give further hints; (cyber-) intelligence may help to reconstruct such events or to track them. All distribution methods and carrier systems have a technology history which gives further directions to the background of an attack.

On the biologic level, microorganisms exist often in variants (strains) which may have been cultivated from precursor strains. The genetic code (DNA) analysis may give hints to the original strains and the sources. Sometimes, microorganisms need a special

preparation for use in attacks which can create a molecular fingerprint and could identify the original production plant. Genetic modifications of bacteria or of bacterial proteins typically result in unique microscopic variations of surface glycoproteins which could be used for production plant attribution like a fingerprint.

Potential Biothreats

Biohacking and Bioterrorism

The typical biohacker works outside established research units or companies as DIY (do it yourself, also DYIBIO) researcher and tries as a kind of ethical hacking to modify genes to invent something useful, but the biohacking scene is closely observed by government authorities. The biohacking scene has made substantial progress in creation of technical equipments (such as thermocyclers for DNA replication), but no critical biohack incident was reported so far.

The other issue is bio-terrorism. The anthrax attacks after 9/11 by sending letters with anthrax-containing powder were done by a bioweapon expert who was reported to have suffered from a psychiatric disorder. The group Aum Shirinkyo was able to conduct terrorist attacks with chemical weapons, but failed with their bio-terrorist attacks. The repeated spraying of anthrax in June and July 1993 in Tokyo apparently caused no reports of diseases or anthrax-related symptoms. In 2013, a man sent letters containing the herbal toxin ricin to parliamentarians and to President Obama. This attempt was detected and failed; the attacker was very quickly identified and imprisoned. A similar attack failed on President Trump in 2018. Another issue is the use of food and water contaminated with infectious agents for attacks, for example, with the bacteria *Salmonella typhimurium* and *Shigella dysenteriae*. In 1984, an intentionally contaminated blue cheese dressing released by two members of the Rajneesh cult led to 751 *Salmonella* cases in The Dalles in Oregon. Infected muffins led to an outbreak of *S. dysenteriae* type 2 in Dallas, Texas in 1996. Recently, a *Shigella* outbreak was reported in Seattle by an infected catering, the investigation is still going on.

Gain of Function-Research

In 2011, the researcher Kawaoka combined an Avian flu and Swine flu virus and showed that this was transmittable between ferrets (which are the animal model for humans due to similar reaction pattern) by droplet transmission. In parallel, the researcher Fouchier showed that Influenza A virus could be much more contagious to ferrets after introduction of certain mutations. Initially, there was a misunderstanding that this virus would also be more aggressive, but this was not the case. This triggered the DURC policy from 2012 and virologists agreed to suspend this gain of function (GoF) research, but 2017 US lifted the ban on GoF funding accompanied by a new regulatory framework on potentially contagious organisms. In short, there are major safety concerns like the inadvertent release from a laboratory while others argue that the nature is driving mutations anyway and that this research is the only chance to be ahead of nature. However, a certain proportion of humans will very likely survive an infection of whatever agent, due to accidental immunity by genetic disposition or genetic defects, by cross-immunity to other agents, by interference with other ongoing diseases, current medication intake or metabolic situations.

Synthetic Biology

Since 2010, Craig Venter worked on a minimal genome cell with the smallest possible genome allowing autonomous life and replication. *Mycoplasma* was used as model organism and in 2016 a new cell, called Syn 3.0 was created with only 473 genes with unknown function of 149 genes. If the function of these 149 genes could be clarified, this could be the breakthrough to designable artificial cells which would be lean and fast replicating.

CRISPR/Cas9

CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats) are DNA sequences in bacteria which help to detect virus DNA from attacking viruses. There are nearby located genes called Cas (CRISPR-associated system), of which the Cas9 type is of practical relevance, as CRISPR/Cas9 can be used in many cells, including human cells. By linking the CRISPR/Cas9 to a synthetic guide RNA, this system can be used for targeted insertion of new and/or deletion of old genes. This technique is much more precise and easier to handle than previous technologies; it allows genome editing (like a draft movie is cut and stuck together) and genome surgery, which is the targeted repair of genetic defects in humans. A biosecurity issue is the potential enhancement of biohacking. The US Defense Advanced Research Projects Agency (DARPA) is currently evaluating Horizontal environmental genetic alteration agents (HEGAAs) as tools to transfer genes into crops to defend them against biothreats, also known as Insect Allies program. With use of CRISPR/Cas9 as part of the research. While DARPA emphasizes the protective potential of this research, concerns were expressed for a potential offensive use as bioweapon or agrarian terrorism tool.

Antimaterial Weapons

The bacterium *Ideonella sakaiensis* 201-F6, discovered in 2016, is able to utilize Polyethylene terephthalate (PET) as energy and carbon source that is used worldwide in plastic products. Other plastic-degrading organisms such as fungi and moths are also

known. Due to the contamination of the environment with plastic garbage, also with microplastic particles, the research on genetically improved plastic-degrading enzymes is in progress. However, such enzymes/agents may have the potential to be antimaterial bioweapons for silent destruction of infrastructure.

Bioluminescence in Eukaryotic Microbes

Jenny Lindström, University of Gothenburg, Gothenburg, Sweden

Michael I Latz, University of California San Diego, La Jolla, CA, United States

© 2019 Elsevier Inc. All rights reserved.

Introduction

Bioluminescence in Eukarya occurs in diverse marine and terrestrial organisms. Light emission exists as long glows or short flashes to serve one, or several, of the many known ecological functions of bioluminescence: defense, camouflage, communication, prey detection, and prey attraction. Bioluminescence is known from ancient times, with accounts of firefly bioluminescence dating back to 1500 BCE and references to ocean bioluminescence as far back as 500 BCE. It is unique from other forms of biological light emission in that the light originates from an enzymatic chemical reaction involving a substrate luciferin and a protein, either luciferase or a photoprotein, within bacterial or eukaryotic free-living cells, or within specialized photocytes of multicellular organisms.

Bioluminescence from microscopic organisms creates sea-sparkle, a globally occurring, nocturnal phenomenon of blue sparkling light in breaking waves or around moving objects (Fig. 1). For centuries the light was attributed to physical or supernatural sources, but only later was the biological source documented; for example 'phosphorescence' in the English Channel in 1810 originated from the dinoflagellate *Noctiluca miliaris* (now *N. scintillans*), first described by naturalist Henry Baker in 1753 as 'animalcules' based on observations with an early microscope.

Eukaryotic luminescent microorganisms consist of dinoflagellates, radiolarians, and phaeodarians. Dinoflagellates are the dominant source of light in coastal and surface waters. Radiolarians contribute mainly to off shore, near surface bioluminescence, while most phaeodarians dwell in deeper water. In these organisms bioluminescence is considered to serve as a defense against predators, and may be a key factor in the success of some dinoflagellate species in competition with other plankton.

Bioluminescence of Radiolaria and Phaeodaria

Radiolarians and phaeodarians are unicellular zooplankton found in all oceans, with the exception of brackish areas. In older taxonomy phaeodaria were grouped with the radiolarians, but they are now within the phylum Cercozoa, while the radiolarians belong to the Retaria, both in the super-phylum Rhizaria. Recent changes in taxonomy affect descriptions of the distribution of bioluminescence in older literature, where no phaeodarian species were considered bioluminescent. Phaeodarians are solitary, while radiolarians live solitary or in colonies. Cells from both groups range in size from 30 μm to 2 mm, and radiolarian colonies can reach three meters in length. Radiolarian and phaeodarian cells are organized in a central and an outer capsule, separated by a membrane. Some radiolarians harbor symbiotic microalgae, e.g., dinoflagellates, in the outer capsule, and their most striking morphological characteristic are the species-specific skeletons of opal-silica or strontium-sulfate (Fig. 2(A)).

Of the 400–800 radiolarian and 400–500 phaeodarian living species, only around a dozen are known to be bioluminescent. Both radiolarian and phaeodarian bioluminescence is triggered by mechanical stimulation. Investigated radiolarians respond with a glow lasting typically 1–2 s, but glows lasting >3 s have also been detected, such as in the colonial *Rhaphidozoum acuferum* and in the solitary *Thalassicolla nucleata*. The light is blue with a relatively short peak wavelength of 440–460 nm, as compared to other bioluminescent members of the marine plankton, such as dinoflagellates, ctenophores, and crustaceans with wavelength maxima of 470–490 nm.

In radiolarians light originates from intercellular structures, "microspheres", located in the outer capsule of the organism, that have the same location as dinoflagellate symbionts. However, it is unlikely that light emission originates from the dinoflagellate symbiont, *Brandtodinium nutricula* (formerly *Zooxanthella nutricula*), which is not known to be bioluminescent, because radiolarian bioluminescence differs from dinoflagellate bioluminescence in its longer flash duration, shorter wavelength, different luciferin type, and lack of pH sensitivity and light inhibition (further described below).

The radiolarian bioluminescence reaction involves the luciferin coelenterazine in combination with a Ca^{2+} -dependent photoprotein or luciferase. Coelenterazine is the most widespread luciferin, also utilized by some crustaceans, coelenterates, squid, brittlestars, and fish. Small crustaceans (copepods) are one original producer of coelenterazine, which is then distributed throughout the food web and obtained by other organisms that have a dietary requirement for the substance. Whether radiolarians are producers or consumers of coelenterazine is not known, but they are unlikely to obtain the substance from copepod prey as these feed on bacteria and other microorganisms.

The ecological benefit of bioluminescence in radiolaria and phaeodaria has not been investigated. Because bioluminescence is mechanically stimulated, it may serve a predator defense function if it is evoked by interaction with a predator and interrupts the feeding behavior of the predator. It is even possible that the radiolarian outer capsule, containing the bioluminescent microspheres, could be shed and left as a glowing lure to confuse the predator. Shedding of capsules occurs in non-bioluminescent radiolarians, but it is not known if microspheres stay functional in a shed capsule.

Fig. 2 Drawings of representative luminescent eukaryotic microbes. (A). Radiolarians. (B). Non-motile, large dinoflagellates. (C). Motile, thecate, small dinoflagellates.

Bioluminescence of Dinoflagellates

Dinoflagellate Characteristics

Dinoflagellates are unicellular plankton, ranging in size between 2 μm and 2 mm in diameter, with complex life cycles involving asexual, sexual, motile, and non-motile life stages as well as resting cysts, depending on species. Some species are obligate autotrophs, or obligate heterotrophs, while others are mixotrophs with the capacity for both photosynthesis and feeding on other organisms. Of the >2300 living dinoflagellate species, sixty nine are known to be bioluminescent.

Common morphological characteristics for dinoflagellates are two flagella, which may not be present in all life stages, e.g., *Pyrocystis* or *Noctiluca*; a large C-shaped nucleus, known as the dinokaryon; and the arrangement of cortical cell membranes called the amphiesma. The amphiesma consist of the outer cell membrane and a layer of flattened vesicles, the alveolae, below which is a pellicle layer. In armoured (thecate) dinoflagellates the alveolae contain cellulose plates, while these plates are lacking in the 'naked' (athecate) dinoflagellates. The dinoflagellate cell contains numerous vacuoles, and vacuolar membranes usually add to the membrane layers of the amphiesma. In bioluminescent dinoflagellates small vesicles known as scintillons, containing the bioluminescence chemistry, are associated with a large acidic vacuole (described further below).

Dinoflagellates have huge genomes of about 3–245 giga base pairs cell⁻¹, arranged in several to >100 chromosomes; for context the human genome is about 3 giga base pairs cell⁻¹. Dinoflagellate genomes are characterized by many redundant and multiple copies of genes. The large genomes, together with a lack of knowledge of dinoflagellate genetic processes, has impaired sequencing efforts, and limits the molecular toolkit available for research on bioluminescent dinoflagellates. To date only genomes of symbiotic species of the genus *Symbiodinium* are fully sequenced, although they are poorly annotated with many genes undescribed. The *Symbiodinium* genome is the smallest in dinoflagellates, perhaps because of its symbiotic life style, and the genus have no known bioluminescent representatives. Dinoflagellate genomic research is increasingly carried out using transcriptomic data.

Dinoflagellate bioluminescence is triggered by mechanical stimulation but spontaneous luminescence, independent of external stimuli, is also well documented. Mechanical stimulation causes flashes of light of 40–500 ms duration with a spectral maximum at 472–474 nm, while spontaneous luminescence can be both short flashes and persistent weak glowing. Stimulated flashes have documented ecological relevance (described below), while the mechanisms for, and potential benefits of, spontaneous luminescence are poorly known.

The bioluminescence of *Lingulodinium polyedra* has been well studied ever since the species was brought into culture by B. M. Sweeney in 1952. This temperate species is around 35 μm in diameter and may form blooms that result in red tides (see below). It is motile, armoured, and autotrophic; some *L. polyedra* strains produce yessotoxins. Other frequently studied bioluminescent species are *Alexandrium tamarense* (autotroph, saxitoxin producer), *Pyrodinium bahamense* (autotroph, saxitoxin producer), *Noctiluca scintillans* (heterotroph, non-toxic), *Pyrocystis lunula*, *Pyrocystis fusiformis* (autotroph, non-toxic) and *Pyrocystis noctiluca* (autotroph, non-toxic) (Fig. 2(B) and (C)). As bioluminescence per cell is related to cell surface area, the smaller *L. polyedra*, *A. tamarense*, *P. bahamense*, and other species of similar size, are often referred to as 'small and dim', while species from the genera *Noctiluca* and *Pyrocystis* are 'large and bright', being about 30 times larger, with 100–1000 times higher light capacity.

Bioluminescence Chemistry

Luciferin, luciferase and luciferin binding protein

Bioluminescence in dinoflagellates involves a unique dinoflagellate luciferin and dinoflagellate luciferases. Luciferin binding protein, which protects luciferin from spontaneous oxidation when light is not produced, is present in all investigated species, except within the genus *Pyrocystis*. Luciferin is highly sensitive to oxygen and reactive oxygen species, while luciferase and luciferin binding protein have pH-sensitive properties that are crucial for the bioluminescence reaction (further described below).

Dinoflagellate luciferin is a linear tetrapyrrole whose structure resembles that of krill luciferin and chlorophyll, a cyclic tetrapyrrole. Its biosynthesis is largely unknown, but like chlorophyll, it is thought to be synthesized as part of the tetrapyrrole biosynthetic pathway. There is currently no evidence for a dietary requirement for luciferin or chlorophyll as a potential precursor of luciferin in dinoflagellates, as the bioluminescence of heterotrophic species can persist when maintained on a luciferin-free non-algal diet.

Luciferase and luciferin binding protein are among the most highly expressed proteins in the cells of luminescent dinoflagellates, with each protein comprising up to 1.5% of the total protein in *L. polyedra*. Luciferase activity is pH dependent, due to histidine residues within the N-terminal region, with no activity at physiological pH and full activity at pH 6.0 or lower due to unfolding of the protein to expose the luciferin binding site. Similarly, the activity of luciferin binding protein is also pH sensitive, with binding at physiological pH and dissociation of the luciferin at pH 7.0 or lower, although the physical structure of the molecule has not been determined to identify the location of the binding site.

Luciferase and luciferin binding protein genes are present in a large number of copies within a species, and sequences can vary considerably between copies; e.g., 10% variation in nucleotide residues in *L. polyedra* or *Alexandrium funydense*. The large interspecies variation is enough to confuse the boundaries between species and even genera in phylogenetic analyses including bioluminescent genes. In *L. polyedra* the luciferin binding protein genes make up two gene families, LBP α and LBP β , which share around 86% similarity and are equally expressed, and in *P. lunula* three distinct variants of the luciferase gene are described, *lcfA*, *lcfB* and *lcfC*.

In photosynthetic species, including *L. polyedra*, the luciferase gene is composed of three domains, each consisting of a highly conserved central region that encodes the catalytic active site, flanked by more variable N- and C-terminal regions with roles in the pH response and activity of the enzyme. These domains are repeated tandemly three times within the same gene, being the template for three equally functional luciferase mRNAs. The heterotrophic *N. scintillans* lacks the tandem repeat of domains and instead has one luciferase gene fused with the luciferin binding protein gene, a second luciferin binding protein gene is located separately in the genome. The arrangement of bioluminescence genes has the potential of providing important insights into dinoflagellate evolution, and conserved regions of the luciferase gene have proven to be useful indicators of the distribution of luminescent dinoflagellates in situ.

Scintillons and activation of the bioluminescence chemistry

Luciferin, luciferase and luciferin binding protein (when present) are densely packed in 0.5–1.5 μm diameter vesicles, known as scintillons or “micro-sources”, structures that are unique to bioluminescent dinoflagellates. Scintillons are formed in association with the Golgi body and are translocated via the cytoskeleton to the cell periphery, where they associate with the vacuole membrane and end up hanging like droplets in the vacuolar space (Fig. 3). Through a thin neck of vacuolar membrane the scintillon content is continuous with the cytoplasm. Thus the scintillons, which have neutral pH, are surrounded by the acid content of the vacuole (pH ~ 3.5).

The pH difference between the vacuole and the scintillons is the key to the bioluminescence activation mechanism. At stimulation of the cell membrane (further described below), H^+ enter scintillons from the acid vacuole through voltage-gated proton channels, following the biochemical gradient. The resultant drop in pH results in release of luciferin by luciferin binding protein, and activation of luciferase to expose the luciferin binding site followed by oxidation of luciferin resulting in a flash of light.

Low pH caused by, e.g., addition of acetic acid to the growth medium or seawater containing dinoflagellate cells, is used experimentally to stimulate maximum light production. This method activates the bioluminescence chemistry directly and bypasses signal transduction pathways activated by mechanical stimulation of the cell, as described in the next section.

Stimulation of Dinoflagellate Bioluminescence

Mechanical forces associated with bubbles, flow or turbulence, and moving objects are sensed by the dinoflagellate cell membrane and activate a signaling pathway that, via multiple intracellular events, leads ultimately to the activation of the bioluminescent chemistry within the scintillons resulting in light emission (Fig. 4).

Fig. 3 Dinoflagellate scintillon formation and association with the vacuole membrane. (A). Hypothesized steps of scintillon formation. (1). Bioluminescent compounds as cytoplasmic condensations in the Golgi area. (2). Formation of scintillons in association with the vacuole membrane and migration to the cell periphery. (3). Mature scintillons. (B). Electron micrograph showing part of a *Lingulodinium polyedra* cell in cross section, with a scintillon (Sc) hanging like a drop within the vacuolar space (V) (inset). Black spots inside the scintillon are immunogold labeling of luciferase. Chloroplasts (Ch) are also shown. Nicolas, M.-T., Nicolas, G., Johnson, C.H., Bassot, J.-M., Hastings, J.W., 1987. Characterization of the bioluminescent organelles in *Gonyaulax polyedra* (Dinoflagellates) after fast-freeze fixation and antiluciferase immunogold staining. Shear stress activation of bioluminescence

Fluid shear stress associated with flow is most effective in stimulating dinoflagellate bioluminescence. Bioluminescence is not activated by typical fluid shear levels found in the ocean interior or within the feeding current of a copepod predator, but requires forces equivalent to an actual encounter with a copepod or breaking waves, $>0.02\text{--}0.3\text{ N m}^{-2}$ depending on the dinoflagellate species. A rapid change in shear stress is more stimulating than slowly developing shear stress, which results in desensitizing of the mechanosensory system.

Cellular mechanism for bioluminescence activation

Cellular mechanisms of mechanotransduction are evolutionary well conserved and allow individual cells in multicellular and unicellular organisms to sense and respond to environmental stimuli. In luminescent dinoflagellates the response latency between mechanical stimuli and a flash of light ranges between 15 and 22 ms for investigated species, including *L. polyedra*, *P. bahamense*, *Alexandrium monilatum*, *P. fusiformis*, and *N. scintillans*, with a minimum latency of only 8 ms. Thus dinoflagellates are capable of rapid mechanosensing.

Mechanotransduction in dinoflagellates is only partly understood, but shares several characteristics with sensing of fluid shear stress due to blood flow in human endothelial cells, and other guanosine triphosphate binding protein (G protein) mediated pathways such as phototransduction in the eyes of fruit flies. Only, the response latency for stimulation of dinoflagellate bioluminescence is shorter than that for sensing of fluid shear in endothelial cells, and even operates more rapidly than photoreception in the fruit fly. Hence, it could be one of the fastest known cellular responses mediated by G proteins in any organism.

From currently available experimental evidence, the following signaling pathway is hypothesized: Mechanical stimulation increases the fluidity of the cell membrane, which activates G proteins directly or via a G protein receptor. G protein activation initiates a series of poorly understood biochemical steps that results in the opening of calcium permeable Transient Receptor Potential channels (TRP channels) located in the cell membrane, via activation of Phospholipase C (PLC), one of the three major G protein second messenger pathways. The open TRP channels allow for influx of calcium across the cell membrane, which in turn stimulates the release of more calcium from intracellular stores.

The increased cytoplasmic calcium concentration leads to depolarization of the electrically excitable membrane of the acidic vacuole, which is associated with the scintillons. Depolarization initiates a self-propagating action potential that travels over the vacuole membrane to open voltage gated H^+ -channels in the scintillon membranes. Influx of H^+ from the vacuole to the scintillons and activation of the bioluminescence reaction as described above.

Intriguingly, genetic studies of dinoflagellate-related organisms suggests that G proteins are lacking in alveolates including dinoflagellates. On the contrary, pharmacological substances that activate or inhibit G protein activity affect bioluminescence (see above) and other activities of alveolates, and a ciliate G protein section has been cloned, suggesting that G proteins may be present in dinoflagellates. Evidence for several types of TRP channels, including motifs conserved from protists to mammals, in an *L. polyedra* transcriptome was only recently discovered.

The cytoskeleton, mainly F actin, serves important functions in the mechanosensing mechanism, possibly by regulating the stiffness of the cell, integrating different parts of the mechanosensing pathway, and/or anchoring the scintillons to the vacuolar membrane.

Circadian Rhythm and Light Inhibition of Bioluminescence

Circadian rhythm

Bioluminescence of the majority of luminescent dinoflagellates follows a circadian rhythm, where the cells are brightly luminescent at night and poorly mechanically excitable during the day. In the dark phase the bioluminescence response to mechanical stimulation is 60–950 times greater than during the day phase, except for a few investigated species, e.g., *N. scintillans*,

that do not have diurnal variations in the bioluminescence response. The day night variation in stimulated bioluminescence is a convenient tool for obtaining luminescent and non-luminescent cells of the same species. This is common and convenient procedures for experimental purposes, as described below in the ecology section. There are two mechanisms that regulate bioluminescence:

- (1) Diel variation of scintillons, luciferin, luciferase and luciferin binding protein.
In *L. polyedra* bioluminescence capacity is diminished by the breakdown of scintillons, and their content, at the end of the dark-phase; the number of scintillons is about 10 times higher in the dark-phase as compared to the light-phase. During the light phase, luciferase and luciferin binding protein are not expressed in the cell, and production is upregulated at the end of each light phase. The expression of luciferase and luciferin binding protein is likely controlled at the translational level, as the level of mRNA templates for these proteins is constant throughout the light and dark phases. The mechanism for translational control is unknown, but there are conflicting reports on a circadian controlled translational regulator (CCTR) for luciferin binding protein in *L. polyedra*, and regulation involving miRNA has been experimentally ruled out.
- (2) Change in scintillon position between light and dark phase.
Members of the genus *Pyrocystis* use a different strategy of scintillon regulation than does *L. polyedra*. *P. noctiluca* and *P. fusiformis* both express luciferase throughout the light and dark phase. The bioluminescent chemistry remains intact in the cell during the dark phase; instead the cellular localization of the scintillons varies with the diurnal rhythm. During the light phase the scintillons are located around the nucleus at the center of the cell. At the beginning of the dark phase, scintillons are translocated via the cytoskeleton to a peripheral position in the cell and are anchored to the membrane of the acidic vacuole. In this position, the bioluminescence chemistry can be activated to produce a flash of light in response to mechanical stimulation. During the light phase the scintillons are not associated with the vacuolar membrane, so action potentials during that phase do not stimulate bioluminescence.

Photoinhibition of bioluminescence

Light exposure during the dark phase inhibits dinoflagellate bioluminescence by as much as 99%. This mechanism of photoinhibition occurs in response to ambient light levels as low as the intensity of the dinoflagellate's own bioluminescence. It is present in heterotrophic and autotrophic dinoflagellates, but absent in some species, e.g., *N. scintillans* and *Polykrikos*. Light exposure affects some component of the mechanotransduction signaling pathway rather than the chemiluminescent reaction, as luminescence from photoinhibited cells can still be stimulated using acid treatment to directly activate the luminescent chemistry.

Inhibition of bioluminescence is complete within 10 min of light exposure, but recovery to full sensitivity takes 30–120 min depending on the level of light exposure and species investigated. Light with a blue emission spectrum is most efficient; inhibiting wavelengths are similar to the absorbance spectrum of chlorophyll, suggesting that the inhibition mechanism involves light absorbance by chlorophyll. However, light inhibition also occurs in several species of heterotrophic dinoflagellates, suggesting that other molecules are light sensitive.

Photoinhibition is one of several physiological mechanisms, including circadian regulation, cell membrane sensitivity, and predator-induced up-regulation of luminescence, all described below, that regulate light emission to minimize the energy spent on bioluminescence in situations where it would not benefit the dinoflagellate. During the dark phase, luminescence intensity in autotrophs is dependent on the energy obtained from sunlight during the previous light phase, and for heterotrophs from prey abundance. In situations when resources are limited dinoflagellates allocate energy to bioluminescence over growth, suggesting that bioluminescence is an expensive but important trait. Existence of non-luminescent strains of otherwise luminescent species may suggest that some strains benefit from mimicry and are able to avoid the energetic cost of producing light.

Ecology of Bioluminescent Dinoflagellates

Worldwide distribution of luminescent dinoflagellates

Dinoflagellates are found in all oceans of the world, with large spatial and temporal variations in abundance. They are the most common source of near-surface displays of bioluminescence, and account for "sheet-like" displays that have been widely observed. Based on observations of *P. bahamense* from bioluminescent bays in Puerto Rico and Jamaica (described below), bioluminescence is observable at cell concentrations $>1000 \text{ cells L}^{-1}$, the blue color of their emission is apparent at concentrations $>6000 \text{ cells L}^{-1}$, and for concentrations $>100,000 \text{ cells L}^{-1}$ the light is bright enough to read by.

Plankton bioluminescence is assessed at night using bathyphotometers that measure flow-stimulated bioluminescence potential across a range of spatial scales. Bathyphotometer measurements has a potential as an early indicator of harmful algal blooms, as described below, as they can indicate low concentrations of the twelve luminescent dinoflagellate species known to be toxic, as well as the presence of non-luminescent toxic species when their abundance is correlated. Bathyphotometer measurements also have potential to assess the composition of phytoplankton communities, and to examine relationships between luminescent populations and oceanographic conditions.

Bioluminescence protects dinoflagellates from copepod grazing

Experimental evidence supports the hypothesis that dinoflagellate bioluminescence serves as a defense against predators. Dinoflagellates in the lower size range (10–50 μm in diameter) are a preferred prey for copepods, compared to other micro/phytoplankton.

Fig. 5 Enhancement of bioluminescence of the dinoflagellate *Lingulodinium polyedra* by copepod lipids. Total bioluminescence capacity assayed by acidification was enhanced 29% from controls following pre-exposure to 1 nM extract of copepod lipids. Modified from Lindström, J., Grebner, W., Rigby, K., Selander, E., 2017. Effects of predator lipids on dinoflagellate defence mechanisms – Increased bioluminescence capacity. Scientific Reports 7, 13104 (9 pages).

Larger dinoflagellates (>50 μm) are too large prey for copepods and are instead consumed by other organisms including hydromedusae, crustaceans, and fish larvae. Although the ecological benefits of bioluminescence in dinoflagellates has been focused on the interaction with copepods, the value of dinoflagellate bioluminescence is less clear against other predators, especially those without visual systems.

Copepods are the most abundant zooplankton in the ocean and thus exert top-down control on dinoflagellate population by grazing. Both *L. polyedra* and *A. tamarense* upregulate their bioluminescence capacity when exposed to lipid compounds released from copepods, while dinoflagellates kept in predator free cultures lose bioluminescence capacity. This suggests that bioluminescence in these species is an effective defense against copepods (Fig. 5).

Bioluminescence reduces grazing from copepods by 50%–80%, as compared to grazing on non-luminescent controls of the same dinoflagellate species. There are three major theories about the predator defense role of dinoflagellate bioluminescence:

- (1) A flash of light from the dinoflagellate interrupt the copepod feeding behavior by startling the copepod.
Copepod swimming behavior is affected by both natural dinoflagellate bioluminescence and artificial flashes that mimic dinoflagellate flashes. Marine and estuarine copepods increase burst swimming behavior when exposed to flash intensities corresponding to flashes from “small and dim” dinoflagellates like *L. polyedra* ($0.002\text{--}0.02 \mu\text{E m}^{-2} \text{s}^{-1}$). This temporarily interrupts feeding behavior of copepods, resulting in reduced grazing. In addition to increased burst swimming, higher light intensities stimulate increased swimming speed and a straighter swimming path that would make copepods both interrupt grazing and potentially swim away from a patch with a high concentration of dinoflagellates. The copepod responses to bioluminescent flashes seem to be specific, as fresh water copepods, with no experience of dinoflagellate bioluminescence, do not respond to flashes.
- (2) The dinoflagellate flash, due to interaction with a copepod, works as a ‘burglar alarm’ that attracts larger predators to feed on the copepod.
Flashes from bioluminescent dinoflagellates have been experimentally demonstrated to make prey (e.g., copepods, mysids, shrimp and fish) more vulnerable to their predators (e.g., fish and cephalopods), and thus are functional as a ‘burglar alarm’. Small and dim dinoflagellates at low concentrations are not effective as a burglar alarm. Instead, inhibition of grazing may be due to the mechanism of aposematic coloration or startling effect. However, as *L. polyedra* and *A. tamarense* are capable of upregulating their light capacity as a response to lipid compounds released from copepods, the burglar alarm effect may be efficient even at lower cell concentrations. The ‘burglar alarm’ effect of the dinoflagellate flash is considered to counteract the tendency for copepods to habituate to the light flash, in which case their risk of predation from visual predators attracted by the flash would increase.

- (3) Bioluminescence works as an aposematic coloration, signaling that the dinoflagellate is toxic.

Bioluminescence works as an aposematic coloration in some terrestrial bioluminescent organisms such as millipedes, signaling the inedibility of the organisms to predators. This mechanism has also been suggested for marine scale worms, brittlestars and jellyfish. As twelve bioluminescent dinoflagellate species are known to produce toxins, and some dinoflagellates also produce other compounds that affect marine organisms, bioluminescence in those species could be effective as an aposomatic signal. Copepod physiology is negatively affected by ingestion of toxic dinoflagellates. But it is unclear if bioluminescence serves as an aposomatic signal in dinoflagellates that results in rejection of toxic cells, as copepods are often capable of recognizing and rejecting toxic dinoflagellates even if they are not bioluminescent.

Red tides and harmful algal blooms

Red tides are blooms of microorganisms, commonly dinoflagellates, that discolor the water because of their high abundance. At night blooms of luminescent dinoflagellates can lead to spectacular displays of bioluminescence, observed in breaking waves, surge, and associated with moving ships and animals.

Red tides or Harmful Algal Blooms (HAB) occur worldwide and are increasing in frequency and distribution, due to increasing ocean temperatures, a higher anthropogenic load of nutrients in coastal regions, and spreading of organisms to new areas via storms and ship ballast water. Red tides of bioluminescent dinoflagellates can be harmless, but also devastating to sea life and affect human health and economy, when blooming species produce potent toxins that are passed through the food chain to be consumed by marine mammals and humans. Even blooms of non-toxic bioluminescent species, e.g., *N. scintillans*, can still have a negative impact on the ecosystem, causing oxygen depletion and increased concentrations of ammonia.

Bioluminescent bays

Unlike typical dinoflagellate blooms, which can be intermittent and unpredictable in occurrence and duration, there are locations known as bioluminescent bays, or biobays, where high abundance of bioluminescent dinoflagellates persists throughout the year. There are fourteen known biobays worldwide, with eleven located in the Caribbean region. The bays are popular sites for ecotourism, and important contributors to the local economies.

Biobays are typically small shallow bays with limited water exchange with the sea, and fringed with a mangrove forest. The understanding of which factors regulates dinoflagellate populations in the biobays are still limited, but common characteristics include; prolonged water retention time, nutrient availability, shallow basin bathymetry, prevailing wind direction that retains organisms with the biobay, and limited tidal range. Mangrove trees are believed to benefit dinoflagellates in two ways: 1. The microbial community associated with the mangroves provides vitamin B12, which is required for dinoflagellate growth, and 2. Phenolic substances derived from mangrove leaf litter inhibits the growth of phytoplankton competing with dinoflagellates for light and nutrients.

The major source of bioluminescence in biobays is the dinoflagellate *Pyrodinium bahamense*, a bloom-forming dinoflagellate found globally in tropical coastal regions and originally described from a biobay in the Bahamas (Fig. 2(C)). The success of this species is believed to be related to its high tolerance for salinity fluctuations; motility that allows cells to relocate to patches with nutrients; and production of saxitoxins that would suppress grazing from copepods. Bioluminescence would also suppress grazing from copepods, as described above, but the relationship between *P. bahamense* abundance and grazing pressure needs to be investigated, because copepods can be very abundant in biobays; for example in Phosphorescent Bay, Puerto Rico, copepod abundance ranges between 20 and 1500 individuals l^{-1} .

Blooms of *P. bahamense* are globally associated with rainfall, most likely due to increased nutrient availability caused by run-off from watersheds. However, in the biobay Laguna Grande in Puerto Rico, daytime monthly abundance of *P. bahamense* measured over three years was not correlated with salinity, nutrients, temperature, or rainfall, although storm events resulted in short-term decreases in abundance.

Applications of Dinoflagellate Bioluminescence

Flow imaging and bioassays

Dinoflagellate bioluminescence is stimulated by a change in flow velocity rather than absolute flow velocity, with an almost instantaneous response, making it useful for the visualization of hydrodynamic stresses and local velocity gradients. Dinoflagellate bioluminescence has been applied as a tool for imaging boundary flows associated with a moving dolphin (Fig. 6) and predicting the luminescent wakes of moving ships, to estimate flow conditions such as stresses within a breaking wave, over a rippled seabed in bioreactors used for cell culture, and associated with a water jet. It has also been used as a bioassay for toxicity, flow stress in microgravity simulators, and detecting magnetic fields. The development of a statistical model for the dinoflagellate flash response provides a theoretical framework for examining the relationship between flow stimulation and the bioluminescence response.

Functions and evolution of cellular mechanotransduction

Dinoflagellate bioluminescence is also a promising experimental system for investigating the evolutionary origins of mechanotransduction in eukaryotes. Mechanosensitive proteins present in dinoflagellates have been evolutionarily conserved and are present in higher organisms including mammals. Dinoflagellate bioluminescence act as a whole-cell reporter of mechanical stress

Fig. 6 Bioluminescence from naturally occurring dinoflagellates stimulated by the motion of an Atlantic bottlenose dolphin *Tursiops truncatus* gliding alongside a boat moving at approximately 0.1 m s^{-1} . The image is from a single video frame taken by a black and white image intensified camera. Reduced bioluminescence on the melon was due to a thinner boundary layer, while flow separation off the fins resulted in enhanced bioluminescence. From Rohr, J., Latz, M.I., Fallon, S., Nauen, J.C., Hendricks, E., 1998. Experimental approaches towards interpreting dolphin-stimulated bioluminescence. *Journal of Experimental Biology* 201, 1447–1460.

where the effects of experimental treatments that target the mechanosensing mechanism are measured as a change in the bioluminescence response to mechanical stimulation. Pharmacological and transcriptomics approaches are providing insight into the structure and function of signaling proteins within the rapid dinoflagellate mechanotransduction pathway.

Education and art

Bioluminescence is a beautiful display of nature that is suitable for educational and artistic purposes. It engages student learning in biology, chemistry, and physics, seeking to answer questions such as: What is bioluminescence? What organisms produce bioluminescence? Where do they live? What is the chemical reaction that results in light emission? What are the functions of bioluminescence? Lessons can be accompanied by classroom demonstrations of dinoflagellate bioluminescence, which can be stimulated by flow, bubbles, or sound, creating opportunities for artistic interpretations leading to creative demonstrations of bioluminescence (Fig. 7).

Bioreactors

Larry E Erickson, Kansas State University, Manhattan, KS, United States

© 2019 Elsevier Inc. All rights reserved.

Glossary

Airlift reactor Column with defined volumes for upflow and downflow of the culture broth; vertical circulation occurs because air is bubbled into the upflow volume.

Batch bioreactor Culture broth is fed into the reactor at the start of the process; air may flow continuously.

Bubble column reactor Aerated column without mechanical agitation.

Fed batch Liquid media is fed to the reactor continuously; the broth accumulates in the reactor as there is no outflow of liquid.

Heterotrophs Microorganisms growing on an organic compound that provides carbon and energy.

Insect cell culture Cultivation of insect cells in a bioreactor to produce a protein or other product.

Photoautotrophs Microorganisms that use light for energy and carbon dioxide for their carbon source.

Plant cell culture Production of plant cells in a bioreactor to produce useful products.

Protein engineering The design, development, and production of new protein products with properties of commercial value.

Tissue engineering The design, development, and production of tissue cells (biomaterials) for use on or in humans.

Introduction

The importance of the bioreactor is recorded in early history. The Babylonians apparently made beer before 5000 BCE. Wine was produced in wineskins, which were carefully selected for their ability to produce a beverage that met the approval of the King and other members of his sensory analysis taste panel. Food and beverage product quality depended on art and craftsmanship rather than on science and engineering during the early years of bioreactor selection and utilization. Early recorded history shows that some understood the importance of the reactants and the environmental or operating conditions of the reactor. This allowed leavened bread and cheese to be produced in Egypt more than 3000 years ago.

The process of cooking food to render it microbiologically safe for human consumption as well as to improve its sensory qualities is also an ancient tradition. The process of thermal inactivation of microorganisms through the canning of food to allow safe storage was an important early achievement in bioreactor design and operation.

As humans learned to live in cities, waste management including wastewater treatment emerged as a necessity for control of disease. One of the first process engineering achievements was the biological treatment of wastes in bioreactors designed and built by humans for that purpose. Because a significant fraction of the population of a city could die from disease spread by unsanitary conditions, these early bioreactors represented important advancements.

After microorganisms were discovered, microbiologists and engineers increased their understanding of the biochemical transformations in bioreactors. Simple anaerobic fermentations for the production of ethyl alcohol, acetone, and butanol were developed. Aerobic and anaerobic treatment of wastewater became widely used. Sanitary engineering became a part of civil engineering education.

In the 1940s, the field of biochemical engineering emerged because of developments in the pharmaceutical industry that required large-scale bioreactors for the production of streptomycin and penicillin. Progress in bioreactor design and control resulted from research on oxygen transfer, air and media sterilization, and pH control. The central concern of the early biochemical engineers was the development of bioreactors that could achieve and maintain the chemical and physical environment for the organism that the biochemist/microbiologist recommended. The ability to scale up from laboratory bioreactors to large fermentors required the development of instrumentation such as the sterilizable oxygen electrode. Early courses in biochemical engineering were concerned with the analysis, design, operation, and control of bioreactors. Bioreactors for mammalian cell applications have been developed and used for health care advances. Stem cell production, tissue engineering, and bioreactors to support regenerative medicine are examples of more recent developments. The liver is a bioreactor, and there is significant progress in the development of bioartificial liver support systems. Some of the significant developments in bioreactor technology are listed in Table 1 together with the approximate date.

Classifications of Bioreactors

Several methods have been used to classify bioreactors. These include the feeding of media and gases and the withdrawal of products; the mode of operation may be batch, fed batch, or continuous. The classification may be based on the electron acceptor; the design may be for aerobic, anaerobic, or microaerobic conditions. In aerobic processes, the methods of providing oxygen have

^aThe dates are approximate and indicative of periods of time when advances were moving from initial studies to published works or commercial use.

resulted in mechanically agitated bioreactors, airlift columns, bubble columns, and membrane reactors. The sterility requirements of pure culture processes with developed strains differ from those of environmental mixed-culture processes, which are based on natural selection. There are bioreactors in which the vessel is made by humans and natural bioreactors such as the microbial cell, the flowing river, and the field of native grass. In this article, the classification of bioreactors will be based on the physical form of the reactants and products.

Gas Phase Reactants or Products

Oxygen and carbon dioxide are the most common gas phase reactants and products. Others include hydrogen, hydrogen sulfide, carbon monoxide, and methane. Oxygen is a reactant in aerobic heterotrophic growth processes, whereas it is a product in photoautotrophic growth. Generally, the concentration of the reactants and products in the liquid phase in the microenvironment of the cell influences the kinetics of the cellular reaction. Mass transfer to and from the gas phase affects bioreactor performance in most processes with gas phase reactants or products. The anaerobic reactor is designed to exclude oxygen. In some cases, inert gases are bubbled into the anaerobic reactor to provide gas-liquid interfacial area to remove the product gases.

Because the solubility of oxygen in water is very low, the dissolved oxygen in the broth is rapidly depleted if oxygen transfer from the gas to the liquid phase is disrupted in aerobic processes. The distribution of dissolved oxygen throughout the reactor volume and the transient variation affect reactor performance. When mold pellets or biofilms are present, the diffusion of oxygen into the interior should be considered. A significant fraction of the bioreactor literature is devoted to oxygen transfer and the methods recommended for the design and operation of aerobic bioreactors. The phase equilibrium relationship is based on thermodynamic data, while the rate of oxygen transfer depends on the gas-liquid interfacial area and the concentration driving force. Mechanical agitation increases the gas-liquid interfacial area. Aeration provides the supply of oxygen, and it affects the gas-liquid interfacial area.

Oxygen has been supplied by permeation through membranes in cultures in which bubbles may damage shear-sensitive cells. The membrane area and concentration driving force determine the oxygen transfer rate in these bioreactors.

Most large-scale bioreactors have either oxygen or carbon dioxide among the reactants or products. In many anaerobic fermentations, the formation of carbon dioxide results in bubbling, and often no additional mixing is required for either mass transfer or suspension of the microbial cells. Methane is produced through anaerobic digestion of waste products. It is also a product of microbial action in landfills, bogs, and the stomach of the cow.

Packed bed bioreactors are used to biodegrade volatile organic compounds in air pollution control applications. The rhizosphere provides a natural environment where many volatile compounds in soil are transformed by microbial and plant enzymes.

Liquid Phase Reactants or Products

Many bioreactors have liquid phase reactants and products. Ethanol, acetone, butanol, and lactic acid are examples of liquid products that can be produced by fermentation. The kinetics of biochemical reactions depend on the liquid phase concentrations of the reactants and, in some cases, the products. The Monod kinetic model and the Michaelis–Menten kinetic model show that many biochemical reactions have first-order dependence on reactant (substrate) concentration at low concentrations and zero-order dependence at higher concentrations. Rates are directly proportional to concentration below 10 mg l^{-1} for many reactants under natural environmental conditions. At very high concentrations, inhibition may be observed.

Hydrocarbons that are relatively insoluble in the water phase, such as hexadecane, may also be reactants or substrates for biochemical reactions. Microbial growth on hydrocarbons has been observed to occur at the liquid–liquid interface as well as in the water phase. The airlift bioreactor is uniquely suited for this four-phase process because of the tendency of the hydrocarbon phase to migrate to the top of the fermentor. The hydrocarbons are found suspended as drops in the water phase, adsorbed to cells, and at the gas–liquid interface. The cells are found adsorbed to hydrocarbon drops, suspended in the water phase, and at the gas–liquid interface. In the airlift fermentor, the vertical circulation mixes the hydrocarbons and cells that have migrated to the top of the fermentor with the broth that enters the downflow side of the column.

One of the oldest and most widely practiced fermentations is the microbial production of ethanol and alcoholic beverages such as beer and wine. Because ethanol inhibits the fermentation at high concentrations, the process of inhibition has been extensively studied for this fermentation. Ethanol affects the cell membrane and the activities of enzymes. This inhibition limits the concentration of ethanol that can be obtained in a fermentor. Because ethanol is also produced for use as a motor fuel, there is still considerable research on ethanol production. Because the cost of the substrate is a major expense, inexpensive raw materials such as wastes containing cellulose have been investigated.

Solid Phase Reactants or Products

There are many examples of bioreactors with solid phase reactants. The cow may be viewed as a mobile bioreactor system that converts solid substrates to methane, carbon dioxide, milk, and body protein. While the cow is a commercial success, many efforts to transform low cost cellulosic solid waste to commercial products in human-made bioreactors have not achieved the same level of success because of economics.

Solid substrates such as soybean meal are commonly fed into commercial fermentations. Through the action of enzymes in the fermentation broth, the biopolymers are hydrolyzed and more soluble reactants are obtained.

Many food fermentations involve the preservation of solid or semisolid foods such as in the conversion of cabbage to sauerkraut and meats to sausage products. Cereals, legumes, vegetables, tubers, fruits, meats, and fish products have been fermented. Some fermented milk processes result in solid products such as cheeses and yogurts.

Other examples include the composting of yard wastes, leaching of metals from ores, silage production, biodegradation of crop residues in soil, microbial action in landfills, and the remediation of contaminated soil.

In many of these fermentations, mixing is difficult or expensive. Transport of essential reactants may depend on diffusion; the concentrations of reactants and products vary with position. Rates may be limited by the transport of essential reactants to the microorganisms.

Most compounds that are present as solids in bioreactors are somewhat soluble in the water phase. For reactants that are relatively insoluble, biochemical reaction rates may be directly proportional to the available interfacial area. The surface of the solid may be the location of the biochemical transformation. An example of microorganisms growing on the surface of a solid substrate is mold on bread. To design bioreactors for solid substrates and solid products, the solubility and the transport processes as well as the kinetics of the process should be addressed.

Recently, there has been considerable progress in tissue engineering. The rational design of living tissues and the production of these tissues by living cells in bioreactors are advancing rapidly because of the progress in systems design and control for both in vitro flow reactors and in vivo maintenance of cell mass. The importance of the local environment with respect to concentration of oxygen, reactants and products must be carefully controlled.

Bioreactors

The rate of reaction in bioreactors is often directly proportional to the concentration of microbial biomass. In biological waste treatment, the influent concentration of the organic substrate (waste) is relatively low, and the quantity of microbial biomass that can be produced from the waste is limited. The economy of the operation and the rate of biodegradation are enhanced by retaining the biomass in the bioreactor. In the activated sludge process, this is done by allowing the biomass to flocculate and settle; it is then recycled. The trickling filter retains biomass by allowing growth on the surfaces of the packing within the bioreactor.

A variety of immobilized cell reactors and immobilized enzyme reactors have been designed and operated because of the economy associated with reuse of cells and enzymes. In the anaerobic production of ethanol, lactic acid, and the other fermentation products, the product yield is greatest when the organisms are not growing and all of the substrate is being converted to products. Continuous processes can be designed in which most of the cells are retained and the limiting maximum product yield is approached. Ultrafiltration membrane bioreactors have been used to retain cells, enzymes, and insoluble substrates.

In nature, cells are retained when biofilms form along flow pathways. The biofilms allow microorganisms to grow and survive in environments where wash out would be expected. The excellent quality of ground-water is the result of microbial biodegradation and purification under conditions where microbial survival is enhanced by biofilm formation and cell retention on soil and rock surfaces. The ability of microorganisms to survive even after their food supply appears to be depleted is well established; this accounts for our ability to find microorganisms almost everywhere in nature. When spills occur, organic substances will often be degraded by microorganisms, if the nutritional environment is balanced. Nitrogen, phosphorus, and other inorganic nutrients often must be added.

The concentration of cells adsorbed to the surface and the concentration in the water phase depend on an adsorption phase equilibrium relationship and the operating conditions. In many environmental applications, most of the cells are adsorbed to surfaces. However, in large-scale fermentors with high cell concentrations and rich media feeds, only a small fraction of the cells are found on surfaces.

In many animal cell bioreactors, cell attachment to surfaces is beneficial and microcarriers are present in bioreactors to provide surface area for cell attachment by adsorption.

Photobioreactors

Light is the energy source that drives photoautotrophic growth processes. Because light is absorbed by the growing culture, the intensity falls rapidly as the distance from the surface increases. Photobioreactors are designed to produce the quantity of product that is desired by selecting a surface area that is sufficient to obtain the needed light. Heat transfer is an important design aspect because any absorbed light energy that is not converted to chemical energy must be dissipated as heat.

There is significant commercial production of algae in open raceway pond photobioreactors that make use of sunlight for the energy for growth. Since temperature is important, these commercial raceway ponds are often in locations where the temperature is in the range from 15C to 35C most or all of the year. Fig. 1 shows the top view of a raceway pond photobioreactor with a paddlewheel to promote flow and mixing for algal mass production. The normal depth of the fluid in the system is about 0.30m. Since the system is open, it is important to have algal biomass that grows rapidly and is able to compete well with other photoautotrophic organisms.

Principles of Bioreactor Analysis and Design

The basic principles of bioreactor analysis and design are similar to those for chemical reactors; however, many biochemical processes have very complex biochemistry. The chemical balance equations or stoichiometry of the process must be known or investigated. The yield of microbial biomass and products depends on the genetics of the strain and the operating conditions. The consistency of data from experimental measurements can be evaluated using mass balances such as the carbon balance and the available electron balance.

Fig. 1 A top view of a raceway pond photobioreactor for algal biomass production.

Microorganisms obey the laws of chemical thermodynamics; some heat is produced in heterotrophic growth processes. The free energy change is negative for the complete system of biochemical reactions associated with heterotrophic growth and product formation. Thus, the chemical energy available for growth and product formation decreases as a result of microbial assimilation of the reactants.

The rate of growth and product formation depends on the number of microorganisms and the concentrations of the nutrients. The kinetics of growth and product formation are often written in terms of the concentration of one rate-limiting substrate; however, in some cases, more than one nutrient may be rate limiting. The kinetics must be known for rational design of the bioreactor.

Heat is evolved in microbial bioreactors. For aerobic processes, the quantity of heat generated (heat of fermentation) is directly proportional to the oxygen utilized. Thus, the heat transfer and oxygen transfer requirements are linked by the energy regularity of approximately 450 kJ of heat evolved per mole of oxygen utilized by the microorganisms.

Transport phenomena is widely applied in bioreactor analysis and design. Many fermentation processes are designed to be transport limited. For example, the oxygen transfer rate may limit the rate of an aerobic process. Bioreactor design depends on the type of organism as well as the nutritional and environmental requirements. For example, in very viscous mycelial fermentations, mechanical agitation is often selected to provide the interfacial area for oxygen transfer. Likewise, animal cells that grow only on surfaces must be cultured in special bioreactors, which provide the necessary surface area and nutritional environment. In other cases, animals are selected as the bioreactors, because the desired biochemical transformations can best be achieved by competitively utilizing animals; cost and quality control are both important when food and pharmaceutical products are produced.

The term biopharming has been introduced to describe the production of proteins for health care applications by transgenic livestock. The product of interest may be produced and separated from milk, for example.

Sensors, Instrumentation, and Control

The ability to measure the physical and chemical environment in the fermentor is essential for control of the process. In the last 60 years, there has been significant progress in the development of sensors and computer control. Physical variables that can be measured include temperature, pressure, power input to mechanical agitators, rheological properties of the broth, gas and liquid flow rates, and interfacial tension. The chemical environment is characterized by means of electrodes for hydrogen ion concentration (pH), redox potential, carbon dioxide partial pressure, and oxygen partial pressure. Gas phase concentrations are measured with the mass spectrometer. Broth concentrations are measured with gas and liquid chromatography; mass spectrometers can be used as detectors with either gas or liquid chromatography. Enzyme thermistors have been developed to measure the concentration of a variety of specific biochemicals. Microbial mass is commonly measured with the spectrophotometer (optical density) and cell numbers through plate counts and direct microscopic observation. Instruments are available to measure components of cells such as reduced pyridine nucleotides and cell nitrogen. Online biomass measurements can be made using a flow cell and a laser by making multiangle light scattering measurements. Multivariate calibration methods and neural network technology allow the data to be processed rapidly and continuously such that a predicted biomass concentration can be obtained every few seconds.

The basic objective of bioreactor design is to create and maintain the environment needed to enable the cells to make the desired biochemical transformations. Advances in instrumentation and control allow this to be done reliably.

Metabolic and Protein Engineering

Genetic modification has allowed many products to be produced economically. With the use of recombinant DNA technology and metabolic engineering, improved cellular activities may be obtained through manipulation of enzymatic, regulatory, and transport functions of the microorganism. The cellular modifications of metabolic engineering are carried out in bioreactors. Successful manipulation requires an understanding of the genetics, biochemistry, and physiology of the cell. Knowledge of the biochemical pathways involved, their regulation, and their kinetics is essential.

Living systems are bioreactors. Through metabolic engineering, man can modify these living bioreactors and alter their performance. Metabolic engineering is a field of reaction engineering that utilizes the concepts that provide the foundation for reactor design including kinetics, thermodynamics, physical chemistry, process control, stability, catalysis, and transport phenomena. These concepts must be combined with an understanding of the biochemistry of the living system. Through metabolic engineering, improved versions of living bioreactors are designed and synthesized.

While many products are produced in microbial cells, other cell lines including insect cells, mammalian cells, and plant cells are utilized for selected applications. The science to support these various living bioreactors is growing rapidly and the number of different applications is increasing steadily. The choice of which organism to select for a specific product must be made carefully with consideration of biochemistry, biochemical engineering, safety, reliability, and cost. Both production and separation processes affect the cost of the product; however, the cost of product development, testing, regulatory approval, and marketing are substantial as well.

Proteins with specific functional properties are being designed, developed, and produced through applications of protein engineering. Through molecular modeling and computer simulation, proteins with specific properties are designed. Protein

production may involve applications of recombinant DNA technology in host cell expression bioreactors. An alternative is to produce a protein with the desired amino acid sequence through direct chemical synthesis.

Stability and Sterilization

While beneficial genetic modification has led to many industrial successful products, contamination and genetic mutations during production operations have resulted in many batches of useless broth. Batch processes are common in bioreactors because of the need to maintain the desired genetic properties of a strain during storage and propagation. Continuous operation is selected for mixed culture processes such as wastewater treatment, where there is natural selection of effective organisms.

Bioreactors that are to operate with pure cultures or mixed cultures from selected strains must be free of contamination, that is, the reactor and associated instrumentation must be sterilizable. The vessels that are to be used for propagation of the inoculum for the large-scale vessel must be sterilizable as well. Methods to sterilize large vessels, instrumentation, and connecting pipes are well developed; however, there is a continuing need to implement a wide variety of good manufacturing practice principles to avoid contamination problems.

Steam sterilization has been widely applied to reduce the number of viable microorganisms in food and fermentation media. As temperature increases, the rates of biochemical reactions increase exponentially until the temperature affects the stability of the enzyme or the viability of the cell. The Arrhenius activation energies, which have been reported for enzymatic reactions and rates of cell growth, are mostly in the range of 20–80 kJ g mol⁻¹, whereas activation energies for the thermal inactivation of microorganisms range from 200 to 400 kJ g mol⁻¹. Many of the preceding principles also apply to the thermal inactivation of microorganisms in bioreactors. When solids are present in foods or fermentation media, heat transfer to the interior of the solid is by conduction. This must be considered in the design of the process because of the increase in the required sterilization time.

Conclusions

Bioreactors are widely used for a variety of purposes. The knowledge base for their application has increased significantly because of the advances in chemical, biochemical, and environmental engineering during the last 70 years. Many different bioreactors have been designed because of the importance of optimizing the production environment within each vessel for each application.

Many pharmaceutical, biomedical, biochemical, food, beverage, fuel, and biomaterial products are produced in bioreactors. The total amount and commercial value of these bioproducts increases annually.

Glossary

Biochips Biochips are biosensor devices with multianalyte capability which integrate biorecognition elements into direct spatial contact with the transducer. These devices typically have biorecognition molecules absorbed/attached to a surface in some sort of array pattern, with the array coded to specific analyte detection at specific sites on the array. The transducer must be able to read out the various signals from specific sites on the array in an independent manner.

Biomimetic In this article, biomimetic refers to synthetic materials/matrices/structures, which in some manner serve to mimic or imitate biological structures found in living systems, although their level of complexity is much reduced from the actual living system. Examples would include liposomes and Langmuir–Blodgett films, which reflect cell membranes, and molecularly imprinted polymers, which imitate biorecognition elements such as antibodies and membrane receptors.

Biorecognition element A biomolecule or synthetic analogue used in a biosensor, which serves the function of recognizing and interacting/binding to the analyte molecule. The selectivity of the biosensor is imparted by the biorecognition element. Examples of biorecognition elements include antibodies, enzymes, nucleic acids, and microorganisms. In this article, biorecognition element and bioreceptor are used interchangeably.

Bioreporters In this context, bioreporters are defined as microbial cells that have been modified by genetic means to express a particular reporter function upon exposure to certain environmental conditions or chemicals/physical stresses. The reporter function may be an enzyme that produces a detectable signal or synthesis of a protein that can be readily detected. Examples of bioreporter organisms would be bacteria that have the luciferase reporter construct linked to a promoter region that responds to some environmental stimulus, and so express bioluminescence when the stimulus occurs, or bacteria that express green fluorescent protein in an analogous manner.

ELISA An acronym for enzyme-linked immunoabsorbent assays. This common type of immunological assay has as its distinctive features the use of antigen-specific antibodies as bioreceptors for the analyte of interest, and the linking of a specific enzyme to at least one of the antibodies forming the immunological sandwich. Addition of the substrate for the enzyme covalently attached to the detector antibody results in an enormous amplification of the signal (detected by optical or electrochemical means, for example) indicating binding between analyte and antibodies, due to the iterative processivity of the enzyme for its substrate. This process thus increases sensitivity of immunoassays.

FRET Abbreviation for Förster Resonance Energy Transfer, sometimes also defined as Fluorescence Resonance Energy Transfer. This process is based on a non-radiative quantum mechanical process which neither requires molecular collisions nor produces heat. FRET can be defined as the distance- and orientation-dependent radiationless transfer of excitation energy from a shorter-wavelength donor to a longer wavelength acceptor. In practical terms, if two fluorophores are close enough together in space (approximately 10 nm or less), and also oriented correctly with respect to the other, then if the higher energy fluorophore is excited, it passes its excited state energy to the lower energy fluorophore via a dipole-dipole interaction. Thus the excitation of the donor fluorophore results in emission of photons from the acceptor fluorophore.

Langmuir–Blodgett films A Langmuir–Blodgett (LB) film is a set of monolayers, or layers of organic material one molecule thick, deposited on a solid substrate. An LB film can consist of a single layer or many. In biosensor applications, biorecognition molecules may be imbedded within LB films, and changes within the film upon analyte binding can be detected by a suitable transducer.

Molecularly imprinted polymers (MIP) Molecularly imprinted polymers are polymers that are formed in such a manner so as to have cavities within them which correspond, in a complementary manner, with specific molecular structures that were used as target molecules when the polymer was formed. Thus, MIP, once formed, become sensing structures that can interact with, and bind, specific molecular species within the specific cavity sites formed during synthesis of the polymer.

Nanoparticles/nanomaterials Nanoparticles are defined as particles in the range of 1–100 nm, while more generally, the realm of nanomaterials encompasses structures in the nanometer size range, that is, submicron sized but larger than atomic dimensions. A great deal of recent interest has focused upon uses of materials in this size range for a variety of applications. For biosensors, nanoparticles with fluorescent properties (quantum dots), magnetic nanoparticles, and nanoparticles derivitized with biorecognition elements may all play increasing roles.

[☆]*Change History:* August 2014. GD Griffin, DN Stratis-Cullum and TE McKnight updated the text and further readings. One author was added to the authorship.

This article is an update of G.D. Griffin, D.N. Stratis-Cullum, Biosensors, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 88–103.

Transducer The transducer is that portion of the biosensor that converts the interaction between the biorecognition element and analyte into a measurable signal. Changes in physical and/or chemical properties such as changes in mass, optical properties, temperature, or electrical properties can be exploited to transduce the interaction of biorecognition element and analyte into a parameter which can be measured by electronic means.

Vesicles In the context of this article, synthetic lipid bilayers in the form of spheres, encapsulating an interior space. Examples would be the many types of liposomes.

GFP	green fluorescent protein
GMOs	genetically modified organisms
LAP	light addressable potentiometric sensor
LB	Langmuir–Blodgett
LNAs	locked nucleic acids
LPS	lipopolysaccharide
MIP	molecularly imprinted polymers
NASBA	nucleic acid sequence-based amplification
PCR	polymerase chain reaction
PNA	peptide nucleic acid
QCM	quartz crystal microbalance
SAW	surface acoustic wave
scFv	single-chain variable fragments
SERS	surface enhanced Raman spectroscopy
SPR	surface plasmon resonance

Defining Statement

Biosensors are integrated analytical devices which use a recognition element, generally a biomolecule, to bind an analyte, and some transduction mechanism to detect this binding event. Details regarding recognition and transduction, as well as applications of such devices to areas such as biomedical applications, food safety, environmental sensing and biological warfare agent detection are discussed.

Introduction/Limitation of Scope

The subject of biosensors is voluminous, with thousands of journal articles (English language only) treating the subject in the last 10 years. Even taking into account that some of these articles use a rather loose definition of biosensors (e.g., not integrated systems), the literature is too extensive to provide an in-depth review for this article. The focus in this article will be on discussion of biosensors of relevance to biology and then on a subset of all potential applications. The overwhelming majority of the current biosensors market is made up of glucose monitors that are used by diabetics for monitoring blood sugar. Since this application has been covered so extensively in numerous reviews, it is omitted here. Also excluded are discussions of biosensors for the wine industry (ethanol sensing) and applications of biosensors to petroleum microbiology.

The biosensing of small molecules of biological importance continues to be the dominant usage in practical medical applications. Thus, sensors for glucose in blood account for ~85% of the world market for biosensors (Ngoepe et al., 2013), due to the prevalence of diabetes. Another major chronic illness, cardiovascular disease, requires monitoring of cholesterol levels. Together, these two biochemical analytes account for the vast bulk of routine biomedical biomonitoring. Nevertheless, earlier biomonitoring for a variety of biomarkers of different diseases has great benefits for the patient, since early intervention can frequently reduce pathological severity and complications. As more understanding develops of underlying pathologies of disease, a greater variety of biomarkers are identified. For some diseases, like cancer, for example, where the underlying pathological basis is still not

understood, identification of robust biomarkers becomes difficult. What is frequently done in such cases is to identify a suite of biomarkers which may be associated with a particular disease process. Integration of diagnostic biosensing and drug delivery is another area which is receiving increasing attention. This is summarized in the word 'theranostics', which incorporates the ideas of diagnosis and therapeutics, and suggests, ultimately, an implantable system which monitors pathological processes, and tailors administered drug regimens to on-going status of the pathology. Suffice it to say that this ideal diagnostic/therapeutic combination is not yet practical, except perhaps in the case of implantable glucose sensors which administer doses of insulin based upon *in vivo* sensing of blood glucose levels. In this review, we focus only on the biosensing arm of theranostics, and do not address drug delivery systems. Beside the standard biosensing technologies such as optical and electrochemical devices, one can also include bioreporter systems, and imaging based biosensors, such as nanoparticles used for defining tumor margins. Indeed, preparation of this review has indicated many ingenious concepts in regard to biosensing.

The incredibly wide range of current developments of biosensing technology, does not, unfortunately immediately translate into practical biomedical devices used in the clinic. Nor is this necessarily the only legitimate use of biosensors. Investigations of fundamental biological processes frequently entail the use of biosensors to reveal the mechanics of the process. Thus, many of the more exotic biosensors which appear in the literature may eventually find their niche for rather unique applications. But, this is not guaranteed. Sensing technologies which require fabrication of components difficult or expensive to produce (or produce in a reproducible manner), or protocols which require much expertise and experience to carry out, may not find widespread use in the biosensing community. Some sensors may remain in the category of laboratory 'curiosities', but it is impossible to predict whether, some day in the future, such 'curiosities' may become eminently practical, as technology advances. We thus attempt to include a very wide range of both biorecognition paradigms and technologies which are being developed, trusting to time and future development to sort out which will become most useful. In some cases, these capabilities are maturing to the point that the notion of 'ubiquitous' biosensing may soon be possible.

There has been an increasing emphasis, in recent years, upon label-free detection of analytes, as opposed to using labels for detection (e.g., fluorescent molecules). Label-free biosensing has become of increasing importance, which in turn has called forth new technologies, in biorecognition, transduction and readout. A very fundamental objection to label-based sensing is that the label itself may introduce changes in conformation of biomolecules, and so may alter the behavior of these molecules in the sensing process. Further, there is an increasing emphasis on *in vivo* sensing prejudices against the use of added molecules which may be toxic. Another two advances in much favor at present are the ability to multiplex (i.e., perform multi-analyte assays simultaneously) and the ability to perform the sensing in real time. The more analytes assayed, the more information, sometimes of a critical nature, is obtained. Real-time monitoring is becoming more important in, for example, diagnosis of pathogen infections, where early detection translates to improved outcomes.

Since understanding of the biorecognition and transduction processes is critical to understanding biosensors, extensive discussion of these topics is included. The various types of molecules which may serve as biorecognition elements are reviewed, and the transduction systems based on the four major categories (i.e., electrochemical, thermal, mass, and optical) are discussed. A recent review (Tamayo et al., 2013), in which the authors tracked the number of publications using various transduction technologies for biosensing, indicated very clearly that optical and electrical-based transduction techniques have dominated in the literature over the past 20 years, with electrical being used most often, followed by optical. The present article also discusses the applications of biosensors to detection of pathogenic organisms or organism toxins in the areas of food safety and biowarfare/terrorism, since these applications have become of great concern. A brief overview of biosensors for environmental monitoring is also provided, although in many such applications, the biosensor is in fact a bioreporter organism, and not integrated into a sensor device. There is also an extensive discussion of new directions in biosensor development, in which topics such as virus-based biosensors, genetically engineered fluorescent proteins as biosensors, and nanotechnology applications to biosensors are reviewed. This article is divided into five main sections: (1) Biosensor Overview, (2) Biorecognition Elements, (3) Transduction Mechanisms, (4) Applications, and (5) New Directions.

Biosensor Overview

Definition

The IUPAC definition of a biosensor is that a biosensor is a self-contained integrated device that is capable of providing specific quantitative or semiquantitative analytical information using a biological recognition element (biochemical receptor) that is retained in direct spatial contact with a transduction element. See Figure 1 for a schematic of how a biosensor works. A common

Figure 1 Schematic diagram of a biosensor.

working definition is that biosensors are analytical devices that use biological macromolecules to recognize an analyte and subsequently activate a signal that is detected with a transducer. However, this common working definition does not suggest an integrated device in which the transducing element is in spatial contact with the biorecognition element. Some authorities subdivide biosensors into affinity biosensors and catalytic biosensors, based on the activity of the biorecognition element. Thus, affinity biosensors have as their fundamental property the recognition (binding) of the analyte by the biorecognition element (e.g., antibody–antigen). Catalytic biosensors have as their biorecognition element as biomolecules, proteins (or microorganisms) that not only bind the analyte but also catalyze a reaction involving the analyte to produce a product (e.g., glucose biosensors). The above discussion does not, however, cover biosensing with bioreporter genes/proteins or bioreporter organisms, nor does it include nanomaterial-based sensors which may be introduced intracellularly to track biological pathways or metabolic processes. We feel it is important to include at least some discussion of such biosensing applications. We do not, however, include imaging techniques *per se*, as this is a vast field in its own right.

Ideal Biosensor Characteristics

Table 1 lists the ideal characteristics of a biosensor. In many cases biosensors are single-use, as the definitions of biosensors do not, in general, explicitly require that the biosensor be regenerable, although for many applications, this is desirable. The ideal biosensor is frequently described as being robust, selective, reproducible, and sensitive with a large dynamic range. This ideal is seldom attained. Bioanalytical systems, such as immunoassays like ELISA (enzyme-linked immunosorbent assay), which may well use the same elements (i.e., bioreceptors and transduction devices), but require additional processing steps, such as reagent addition and washings, and usually involve reading the completed assay on some separate piece of instrumentation, are to be distinguished from biosensors. Thus, the very large opus of experimental literature describing the use of immunoassays, nucleic acid-based assays, and so on for detection of various analytes does not necessarily describe biosensors, *per se*, although the techniques described in such assays may well have application in the development of actual biosensors.

Assay Formats

In general, a variety of assays can be employed with the many different biorecognition and transduction elements described below. There is not sufficient space to provide anything more than a very general overview of the assay formats involved in biosensing. Briefly, the assay formats can be either direct or indirect. In the direct methods, analyte binding to the biorecognition element is detected directly, by such techniques as mass changes, changes in refractive index or impedance, pH, and so on (Figure 2). For indirect techniques, an additional reaction (other than the biorecognition binding event) has to occur in order to detect the binding of analyte and bioreceptor. In a competitive indirect strategy, the analyte and a competitor molecule (labeled in some fashion) compete for limited numbers of biorecognition binding sites (Figure 3). In the noncompetitive indirect assay, a second biorecognition element with a label is added to the analyte sample, so that when the analyte binds to the immobilized biorecognition element, the second biorecognition element also binds to the analyte (Figure 4). In the case of labels for the indirect type of assay, the label can be optical-, electrochemical-, or mass-related. In the case of direct assays and noncompetitive indirect assays, the signal is directly proportional to the analyte concentration, while in the case of competitive indirect assays, the signal is inversely proportional to analyte concentration. Frequently also, biosensor assay formats involve some form of amplification, the rationale

Table 1 Ideal biosensor characteristics

Characteristic	Description
Analysis time	A fast analysis time is desired, with 'real-time' responses to target analytes ideally desired
Sensitivity	A sensitive analysis allows for detection of low concentrations of target analytes and leads to low false-negative analyses
Specificity	A specific analysis allows for discrimination between target analytes and other closely related species and minimizes false-positive analyses
Reproducibility	The analysis should be highly reproducible, to provide for a reliable analysis that is easy to calibrate
Accuracy	The biosensor device should be highly accurate, meaning false-positives and false-negatives are minimized
Robustness	The biosensor must be insensitive to environmental conditions (temperature, pH, electronic interferences, etc.)
Unit and operational costs	A lower unit cost and operational costs for reagents, and so on will allow for more wide spread implementation of the biosensor systems
Size and weight	The ability to miniaturize a biosensor is desired, particularly for integration into process monitoring applications as well as for field portable applications
Regeneration	The ability to regenerate the binding surface, allowing multiple measurements by the same sensor element is preferable, although single-use platforms are sometimes sufficient
Multianalyte detection	A biosensor that can detect multiple analytes simultaneously is highly desired for efficient cost, time, and size and weight utilization
Adaptable	A flexible biosensor platform is highly desired, especially when considering the need to quickly adapt sensing modalities to respond to new threats as they emerge.
User interface	Ideally, fully automated systems are desired, or at the minimum require little-to-know operator skills for routine analysis

for this being increased sensitivity of the assay. Either the analyte molecules themselves may be amplified (e.g., polymerase chain reaction (PCR) of DNA sequences) or the biorecognition event may be amplified (e.g., ELISA immunoassays).

Biorecognition Elements of Biosensors

The biorecognition element of biosensors has classically been some natural biomolecule, antibodies being the most common example. However, biorecognition elements also include bioreceptors such as enzymes, nucleic acids, peptides, and receptors that reside in the membranes of cells, and even larger biological units, such as whole cells. The biorecognition element plays a crucial role to the overall biosensor performance, imparting selectivity for a particular analyte. If the definition of biorecognition elements only includes natural biomolecules (up to the collection of biomolecules comprising a whole cell), such artificial recognition elements as imprinted polymers or peptide nucleic acids (PNAs) would be excluded. This rigorous definition seems too restrictive, however, and in this article, the authors include biosensors using such biorecognition elements as synthetic peptides, aptamers, PNAs, liposomes, and molecularly imprinted polymers (MIP). A brief description of the various types of biorecognition elements will now be given.

Figure 4 Schematic diagram illustrating an indirect assay with noncompetitive binding.

Antibodies

Antibodies are proteins produced by the immune system that have as their unique feature antigen recognition sites that bind antigens by noncovalent interactions in an exquisitely specific fashion and often with relatively high affinity. The antigen-binding portions of the molecule are the V_H (heavy chain variable region) and the V_L (light chain variable region) regions, which both fold to provide a sort of 'lock and key' fit for the specific antigen. Included in antibody categories would be polyclonal and monoclonal antibodies. Antibodies are probably the most commonly used of all biorecognition elements for sensor applications. Frequently, sensor design makes use of antibody 'sandwiches', where, for example, capture antibodies immobilize the analyte, while other labeled detector antibodies bind to the analyte and thus provide a sensing signal. It is also common to use some sort of amplification technique (e.g., enzymes-ELISA assays) to provide a more robust signal of the recognition process. Ingenious combinations of nucleic acid and immunological techniques (e.g., immuno-PCR and immuno-rolling circle amplification) can also be used for amplification.

Antibody fragments/engineered antibody fragments

For biosensing applications, the molecular recognition site(s) of the antibody (the antigen combining sites) are of overwhelming importance, while the function of the Fc region, of importance physiologically, may not be required for sensing applications. Also, antibodies are often immobilized on solid substrates for sensing applications, and here the orientation of the antibodies is as critical as the antigen combining site should ideally be oriented in a spatially accessible manner. Thus, smaller antibody fragments may have certain advantages, such as more defined points of immobilization through thiol groups liberated after cleavage of the whole immunoglobulin molecule, and also these fragments could be more densely packed upon a sensor surface, thus increasing the epitope density over that found with intact immunoglobulin and so perhaps enhancing sensitivity. Enzymatic cleavage of immunoglobulin molecules to produce fragments such as Fab (antigen-binding fragment) is one way to produce these smaller recognition elements. Using the techniques of phage display or ribosome display for antibody gene cloning and expression, antigen-binding fragments of antibody molecules called single-chain variable fragments (scFv) can be obtained. These fragments feature the V_H and V_L domains joined by a flexible polypeptide linker which can be engineered to have desirable properties for immobilization (e.g., a thiol group of cysteine). Some studies have found the scFv antibody fragments to be superior to either the Fab fragment or the whole immunoglobulin molecule for sensor applications.

Enzymes

Enzymes are catalytic proteins that have an active site that shares some of the features of the antigen-binding site of antibodies, that is, exquisite specificity for certain molecular structures, referred to as their substrates. Again, genetically engineered enzymes with altered properties can be used. Enzymes are not frequently used as biorecognition elements, *per se*, but are usually a component of a multiple molecular biorecognition package, where the enzyme is included to provide amplification (such as in ELISA immunoassays or coupling to an electrochemical detection transduction system (e.g., horseradish peroxidase and urease for electrochemical detection schemes)). An example where an enzyme functions as a direct biorecognition element would be the use of cholinesterase enzymes to detect certain organic phosphate pesticides/chemical warfare agents that are cholinesterase inhibitors.

Proteins/Peptides with Specific Binding Properties

Phage display

Using techniques developed in recent years, it is now possible to produce and evolve peptides/proteins with strong binding affinity for specific proteins. These techniques include phage display and ribosome display. It is outside the scope of this article to provide an in-depth review of these procedures. In each technique, iterative rounds of affinity purification enrich for proteins/peptides with desired binding properties for a specific ligand. The unique feature of phage display is that the production of 10^7 – 10^8 short peptides on the surface of filamentous bacteriophage can be achieved through the fusion of an epitope library of DNA sequences with the gene(s) coding for one of several coat proteins (the minor coat protein, phage gene III, was used initially). An epitope library of such cloning can display 10^7 or greater peptides that can be panned for peptides that bind specifically to an analyte of interest. Proteins made from the phage display technique have been used to detect bacteria, bacterial spores, toxins, and viruses.

Bacterial display

Although biorecognition has shown the potential to meet many of the desired features outlined in Table 1, a key advantage of many synthetic reagent technologies is the speed at which they can be discovered (Stratis-Cullum and Finch, 2013). This is particularly critical when considering rapidly changing detection needs, including having the ability to sense newly engineered threat agents to which no current biosensor or biomolecular receptor exists. For example, antibodies (including engineered antibodies) usually require several weeks if not months to isolate from living hosts, whereas recent advances have demonstrated that synthetic routes can be employed using various synthetic peptide recognition element technologies (e.g., bacterial display and phage display) to produce bioreceptors in as little as a few days to a couple of weeks (Kogot et al., 2011; Stratis-Cullum et al., 2012, 2010, 2011).

The mechanisms for specific binding with peptides (protein building blocks) are similar to antibody-antigen interactions, and synthetic peptide receptors show some of the greatest potential as synthetic antibody alternatives (Pavan and Berti, 2012). Although, several variations of combinatorial peptide technologies, including yeast, phage, and bacterial display and other chemically synthetic techniques, are currently used to isolate synthetic reagents, bacterial display with unconstrained bacterial peptide display technology shows great potential. In this work, the extremely fast replication rate of bacteria and biological components (e.g., modified proteins) on an *E. coli* cell surface are harnessed to produce the peptide library of binders (Daugherty, 2007; Kogot et al., 2011; Stratis-Cullum et al., 2012). Another unique feature is the ability to normalization for the expression level—a key enabling feature for reproducible, quantitative reagent discovery. Although discovery is rapid and easily automated using bacterial display technology, the characterization, optimization, and integration into assays and devices can still be a bottleneck to successful biosensor development using synthetic alternatives.

Protein catalyzed capture agents

More recently, advances in peptide *in-situ* click chemistry have allowed for development of highly manufacturable and highly selective synthetic antibody alternatives known as protein-catalyzed capture (PCC) Agents (Farrow et al., 2013; Millward et al., 2013, 2011). With PCC technology, the target protein is used directly as a catalytic scaffold for assembling in a stepwise fashion, synthetic anchor, and multiligand systems. PCC agents are assembled from comprehensive, chemically synthesized peptide libraries that incorporate non-natural amino acids into the starting library to produce a final product that is highly stable. Additionally they serve as synthetic ‘drop-in replacements’ that are highly adaptable and easily integrated into assays and sensor systems. The process is repeated to build biligand and triligand structures, or alternatively advanced libraries can be used. In either case, each subsequent ligand modification, serves to refine the binding affinity and specificity through avidity with the target. The final synthetic peptide can be scaled up on-demand by automated chemical synthesis, avoiding the problem of batch-to-batch reproducibility. Recently, this technology has been shown for protective antigen, for *Bacillus anthracis* where the remarkable temperature stability is also highlighted (Farrow et al., 2013).

Nucleic Acids

Included here are oligo- or polynucleotides such as DNA and RNA. DNA is used more frequently due to its inherent greater stability under a variety of conditions. The biorecognition process consists of noncovalent interactions between bases of complementary nucleic acid strands by Watson–Crick base pairing rules and is manifested by hybridization of two single strands having such complementary base sequences. Exquisite specificity can be obtained due to the cumulative specific interaction of many bases to their complementary units on the other polynucleotide chain. Nucleic acid sensors are frequently coupled to schemes that utilize amplification of diagnostic nucleic acid sequences (e.g., PCR, nucleic acid sequence-based amplification (NASBA), and rolling circle amplification) with the potential for extreme sensitivity, since a large number of copies of an initially low copy number sequence can be obtained by amplification techniques.

Aptamers

Aptamers can also be included as nucleic acid biorecognition elements, since they are made up of single strands of nucleic acid (DNA or RNA), but here the biorecognition is not via base pairing but by folding to form a unique structure. In contrast to base pairing as the biorecognition feature, the aptamer folds in such a manner that it forms a highly specific three-dimensional structure that recognizes a specific analyte molecule, somewhat similar to the nature of the antibody–antigen interaction. Aptamer selectivity

and binding affinity can be similar to the specificity and affinities of antibodies. An advantage of aptamers over antibodies is that the aptamer structure is inherently more robust than the antibody quaternary structure, so that aptamers can be subjected to numerous rounds of denaturation and renaturation, thus providing for easy regeneration of the sensor as well as an overall more robust biosensor. Antibodies are fundamentally products of animal immune systems, with all the limitations that implies. Aptamers are produced by chemical synthesis after selection rather than via immune system cells, and so can be readily modified to enhance stability and affinity. Also, aptamers can be selected against certain targets that can cause the immune system to fail to respond, such as bacterial toxins or prions. Because of all these advantages, aptamers are being used increasingly as biosensor elements. Aptamers have been increasingly utilized for small biomolecular sensing in recent times. Antibodies can be developed against small molecules, but are not, in general, the most effective biorecognition elements for such applications. Aptamers are smaller in molecular size and more stable than antibodies, can be modified with various tags more readily and with less chance of disrupting the recognition site than antibodies, and can be produced to recognize small molecules such as metal ions, or biomolecules such as ADP and ATP. Various transduction schemes can be utilized to signal binding of aptamer to target, including FRET-based assays, relying on aptamer conformational changes produced by target interaction, or generation of DNazymes, or separation of the aptamer into two components, which are reunited upon target binding, and thereby produce a transducing signal.

Among interesting developments has been the design of RNA sensors, which combine aptamers with ribozymes (catalytic RNAs) to produce RNA molecules (these structures have been called aptazymes) whose catalytic activity depends in some manner upon binding of a specific ligand, the analyte. The binding of the analyte can either stabilize or destabilize the catalytic domain and so adjust the catalytic activity. Thus detection of the analyte species is signaled by changes in the enzyme's activity.

A quite unique aptamer approach described by [Paige et al. \(2012\)](#) is the development of what might be termed a 'dual-function' RNA aptamer. These investigators previously developed an aptamer that would specifically bind a small organic fluorophore in a specific location, and so switch on its fluorescence, somewhat analogous to the photo-active center of the naturally occurring green fluorescent protein. They were able to fuse this RNA with another aptamer which had small molecule (e.g., S-adenosyl methionine [SAM], GTP, ADP) binding properties. Upon binding of the analyte ligand, the analyte-recognizing portion of the composite aptamer folded in such a way as to stabilize the fluorophore-binding stem of the composite structure, thus turning on fluorescence (upon addition of the fluorophore) as an indicator of analyte binding. Of course, development of this composite sensing molecule required a great deal of molecular biology manipulation. The authors were able to demonstrate detection of production of the SAM metabolite *in vivo*, using *E. coli* which expressed the composite RNA aptamer. They noted that fluorescence increases of ~20-fold could be produced upon analyte binding to these sensors, a much more robust response than FRET-based systems for detecting small molecules such as metabolites. It should be noted that use of the sensor *in vivo* was only demonstrated in cells which genetically expressed the sensor, and in this case, were *E. coli*.

Peptide nucleic acids

PNA structures are not strictly natural biorecognition molecules, since they are a hybrid of a series of *N*-(2-aminoethyl)-glycine units making up the backbone structure (instead of the sugar-phosphate backbone of natural nucleic acids) with the standard bases bound to the peptide backbone. All intramolecular distances and configurations of the bases are similar to those of natural DNA. Thus, hybridization to DNA or RNA molecules is readily achieved. Since the PNA backbone is uncharged, PNA-DNA duplexes are more thermally stable than DNA-DNA duplexes, and so single-base mismatches have a more destabilizing effect in PNA-DNA hybrids. The PNA structure is stable over a wide temperature and pH range and resistant to nuclease and protease activity and so has obvious applications in the biosensor area. Also, PNAs can be used for the detection of double-stranded DNA directly, eliminating the requirement for thermal denaturation, due to the ability of PNAs to form higher order complexes (three- and four-stranded) with DNA.

Also to be mentioned are another type of nucleotide analogue called locked nucleic acids (LNAs). These nucleic acid analogues have modified RNA nucleosides where a ribonucleoside has a methylene linkage between the 2'-oxygen and the 4'-carbon. These LNAs have the usual hybridization properties expected of nucleic acids with other desirable properties such as highly stable base pairing, high thermal stability, compatibility with most enzymes, and predictable melting behavior.

Molecular beacons

This is a subset of nucleic acid biorecognition molecules, generally synthetic oligonucleotides that are designed to have a hairpin (stem-loop) structure. The loop contains a nucleotide sequence complementary to the analyte sequence to be detected, while the stem structure has only a small number of complementary bases, forming a short double-stranded portion. Fluorophore and quencher molecules are held in close proximity on the two ends of the double-stranded stem, when the molecular beacon is in the closed position. Upon binding of the analyte sequence to the loop portion, the stem opens, the quenching effect on the fluorophore is relieved and the resulting fluorescence signals the presence of the analyte sequence. Aptamers can also serve as molecular beacon biosensors, with this important distinction, that they can be used to detect non-nucleic acid analytes, such as proteins or small organic molecules. PNAs can also be used to form molecular beacon-type structures, and these can be stem-less, in contrast to the usual stem-loop structure found in natural DNA molecular beacons. This stemless structure has advantages (less sensitive to ionic strength, quenching not affected by DNA-binding proteins) as compared to the initially designed DNA beacons. Molecular beacons have generated great interest because of their potential to investigate cellular mechanisms, particularly with regard to genetic expression events. A recent review provides an in-depth look at what the authors refer to as oligonucleotide optical switches, referring to the fact that these probes switch on (or off) optical response in response to molecular interaction with specific targets

(see Giannetti et al., 2013). Besides the standard stem-loop structure, other configurations are implemented to accomplish the same optical switching effect. Thus, so-called binary probes have been used to detect mRNA expression inside cells. In this case, a probe structure is constructed such that two oligonucleotide segments, which are complementary to adjacent sequences on the mRNA target, are labeled with a donor and acceptor fluorophore respectively, and are linked by a longer PEG spacer. The spacer keeps the donor and acceptor fluorophore apart so that FRET cannot occur. If hybridization to the target mRNA occurs, however, the acceptor and donor are in close apposition, and FRET can be detected.

In an even simpler design, called nanoflares, the probe oligonucleotide is hybridized to a short complementary oligonucleotide (called the reporter) with an attached fluorophore. One free end of the probe oligonucleotide is attached to a gold nanoparticle, thus quenching the fluorophore's fluorescence. Upon hybridization of the target nucleic acid, the reporter is displaced, because of a more stable hybridization with the longer target sequence, and the fluorescence of the fluorophore attached to the reporter is restored. An analogous concept can be used with aptamers to detect protein targets. Although in principle the molecular beacon concept seems very versatile, there are problems. These exogenous nucleic acids can be susceptible to endogenous nuclease degradation, the signal intensity can be low, due to limited numbers of fluorophores (only one per probe molecule) and the quenching effects are not 100% effective.

Cell Surface Receptors/Glycoproteins, Glycolipids/Glycans

Many of the molecular recognition events having to do with cell–cell interaction, pathogen attack upon cells, and so on take place in the glycocalyx layer of the cell membrane. The glycocalyx layer consists primarily of oligosaccharide headgroups of glycoproteins and glycolipids. The lipid or protein portion of these molecules is embedded in the membrane, while the hydrophilic oligosaccharide chain is extended into the outer environment. As the molecular biology of pathogen and toxin interaction with the cell surface is elucidated at the molecular level, these receptor molecules are receiving increasing attention as biorecognition elements. One of the major difficulties heretofore with exploitation of these receptors is the complexity of the cell membrane, making mimicry of this structure a daunting task. Simpler models of cell membranes with defined chemical compositions include liposomes (vesicles) and Langmuir–Blodgett (LB) monolayers. Recent advances have formulated biorecognition molecules into these synthetic lipid structures. In some cases, pathogens or toxins produced by pathogens target specific cell surface receptor sites. These same cell-based receptors can then become biosensor recognition elements. Thus, biorecognition elements seeing use in sensors include gangliosides, glycosphingolipids that are localized upon certain cell types, as well as carbohydrate/oligosaccharide structures found on the cell surface. For example, ganglioside GT1b has been used as a recognition element for botulinum toxin, while *N*-acetylneuraminic acid and *N*-acetylgalactosamine bound cholera and tetanus toxin, respectively, in a semispecific manner. Uropathogenic *Escherichia coli* strains attach to uroepithelial cells by adhesion to the glycolipid globotetraosylceramide (globoside), and so sensors for these *E. coli* strains can be formulated using this globoside. Human gastric mucin has been used in a biosensor format to study the interaction of *Helicobacter pylori* with the extracellular matrix components. Lectins, a broad class of proteins/glycoproteins that bind with high affinity to specific carbohydrate moieties, have also been incorporated into biosensing devices.

Often, oligosaccharides form primary molecular components and markers on pathogen surfaces, and thus may form the basis for diagnostic sensors for specific bacteria or groups of bacteria. For example, the lipopolysaccharide (LPS) molecules (commonly known as bacterial endotoxin), which are found on the cell surface of Gram-negative bacteria, can serve as targets for biorecognition by lectins or other proteins. See sections 'Liposomes' and 'Biomimetic Materials' for further discussion on this topic.

Olfactory Receptors

Biosensors based upon olfactory receptors (OR) are generating increasing interest. These sensing elements are situated in the nasal epithelium and have the ability to respond selectively to thousands of low-molecular weight organic compounds. Cell and tissue-based olfactory biosensors have the advantage of retaining the complex biological structural integrity of the intact olfactory system, but have the great disadvantage of requiring demanding culture conditions to function normally. A more practical approach has been to use olfactory receptors and/or olfactory-based proteins. Probably the most practical method of generating reasonable amounts of one specific OR is, by genetic engineering, to express this OR heterologously in various cell lines, from which the active OR can be extracted, retaining its native conformation and activity. Cell-free protein synthesis is also a route to produce ORs, or, whole cells can be used as biosensors, in which the OR's are expressed, through gene transfer, on the cell membrane. So far, the fragility (ease of denaturation) of the odorant-detecting proteins themselves, has been a major obstacle to use in durable biosensors. With development of basic understanding of the olfactory process on a molecular level, synthetic peptides having OR properties will become increasingly important. Several examples of chemicals which have been detected by OR-based sensors include acetic acid, hexanal and octanal.

Whole Cells

In some ways, whole cells do not fit the strict definition of a biosensor biorecognition element, since they are most often used to function as 'bioreporters'. That is, the cells are genetically altered to synthesize a certain marker that produces a detectable signal of some sort (i. e. luminescence and fluorescence) when they encounter specific compounds/environmental conditions. Such whole cell sensors have been applied to environmental analysis and monitoring. A brief description of such applications is included later

in this article (see Section [Bacterial Biosensors for Environmental Monitoring](#) under Section [Applications of Biosensors](#)). There are, however, some examples of whole cells being used as biosensors, particularly microbial cells. Often in these instances, the whole cellular machinery functions in a sense as a biorecognition/processing system for the analyte, as, for example, using bacterial cells induced to constitutively produce an amino acid-metabolizing enzyme to detect that particular amino acid. Another innovative approach using whole cells is to genetically engineer cells of the immune system to respond to specific pathogen binding events by producing a detectable signal from some genetically inserted reporter construct.

Either microorganisms or mammalian cells can potentially be used as cell-based sensors.

Microorganism-based sensors have a variety of advantages over mammalian cells, such as much better stability in harsh environments, relative ease of mass production, and ease of genetic manipulation. The most common employment of these entities is either in optics-based or electrochemical-based biosensing. Electrochemical sensing can involve either production or consumption of electroactive species which can be detected by conductimetric, amperometric or a variety of other electrical techniques. Optical sensing usually involves the genetic modification of the sensor microbe, so that in some manner an optical signal is produced upon interaction with a specific analyte. [Park et al. \(2013\)](#) provide a recent review of many such optically-based sensors. One strategy is to make use of reporter genes, whose protein products are under the control of a specific regulatory pathway, which pathway can be induced by an analyte or analytes of interest. Thus, a common approach is to use a transcriptional regulator (e.g., repressor) and promoter whose induction is linked to, for example, external chemicals, or specific nutrients, or antibiotics or signaling molecules, etc. When the analyte to be detected is present, the repression of the promoter is removed and the resulting induction results in expression of the reporter gene. Beta-galactosidase is one such reporter protein: since it is an enzyme, there is great amplification attendant upon its expression, and a wide variety of substrates offer great flexibility in detection. Another widely used genetic reporter system are the various luciferases, be they bacterial, or from *Renilla reniformis* (sea pansy) or from the firefly. The introduction of the bacterial lux operon into a microbial host produces a light-generating enzymatic reaction which does not require addition of an exogenous substrate. Firefly luciferase, introduced as a reporter gene, requires addition of a substrate, luciferin, but has the advantage of a higher quantum yield than bacterial luciferase. Linking metallothionein promoters with firefly luciferase was carried out to develop a heavy metal biosensor, using *Tetrahymena thermophila*. Fluorescent proteins originally isolated from various marine organisms can also serve as valuable reporter gene constructs, and genetic engineering has produced artificial versions of these proteins which have superior optical properties compared to the natural proteins. Analogous to the reporter gene systems discussed above are ribosomal switches or riboswitches, which consist of an aptamer domain linked to a reporter gene. Binding of analyte to the aptamer results in a conformational change in the aptamer, thereby triggering expression of the protein product of the reporter gene.

Bacteriophage

Bacteriophage, by virtue of the fact that they recognize in a specific manner their host bacteria, can become biorecognition elements. The bacteriophage themselves may be used, with appropriate labels (e.g., fluorescent dyes) to detect the binding event, or the phage may be selected for binding to a specific analyte via fusion proteins on the phage coat (i.e., phage display). This latter paradigm has even been extended to expression of the biorecognition peptide as an N-terminal add-on to the major coat protein of the phage. In this case, there is a display of thousands of copies of the recognition protein on the phage surface, thus potentially greatly increasing the sensitivity of the assay by increasing the density of the epitopes displayed. Thus, the phage themselves become both biorecognition (by virtue of peptides displayed on their surface) elements and amplification (multiple copies of fluorescent dye per phage) elements. This type of biosensor could be considered a whole cell biosensor (bacteriophage) that has a bioreceptor on its surface.

Biomimetic Materials

Biomimetic strategies are becoming more varied at present. Besides molecularly imprinted polymers (MIP), which aim to generate a fully artificial, negative macromolecular mold of an analyte, polymer coatings are being investigated which change the biocompatibility of surfaces and thus permit immobilization of receptors or ligands in a more 'natural' setting. Such materials could either be membrane mimics (for example, liposomes) or self-assembled monolayers. Also, using computer simulations, it is becoming possible to identify peptides, DNA fragments, enzymes or smaller portions of receptors which make up the functional biorecognition sites of proteins, or other bioactive species, and so use these molecular fragments as biomimetic sensors. Also, nanoparticles, nanomaterials and nanocomposites may be used as biomimetics.

Liposomes

Liposomes are synthetic lipid vesicles, mimicking in some respects cell membranes, although not nearly as complex. Liposomes are frequently used as components of biorecognition systems, but usually the liposomal membrane structure is modified with a standard biorecognition element such as an antibody or oligonucleotide, and these molecules provide the specific recognition. In such cases, the liposome may have encapsulated fluorescent dyes, enzymes, electrochemically active species, and so on, which, upon biorecognition, may be released, and thus the liposome itself functions as an amplification system. More direct involvement of liposomes as sensing elements *per se* are occasionally also encountered. For example, insertion of the ganglioside GM1 into the liposomal membrane has been used to develop a sensor for cholera toxin, since the GM1 has specific affinity for cholera toxin. In a similar vein, liposomes containing cholesterol in the membrane could function as sensors for the toxin listeriolysin.

Molecularly imprinted polymers

A recent development that may, in the future, provide artificial macromolecular bioreceptors is the technique of molecular imprinting. In this procedure, a target molecule (i.e., the analyte), acting as a molecular template, is used as a pattern to direct the assembly of specific binding elements (i.e., monomeric units) that are subsequently polymerized with a cross-linker. The interaction of the monomeric units with the template molecule may be either through noncovalent (the more usual) or covalent bonding. Following polymerization, the target molecule is removed from the polymeric matrix (by suitable solvent or chemical cleavage) leaving a cavity within the polymeric matrix, which is a molecular 'negative' image of the target molecule. The monomeric subunits that interact with the target molecule in a noncovalent molecular imprinting scheme do so by interactions such as hydrogen bonding, van der Waal's forces, and hydrophobic interactions, just as antibody-antigen interactions take place. The subsequent interaction with the cross-linker freezes the binding groups in a specific orientation. Ideally, once the target molecule is removed from the polymer, a binding site now exists which is complementary in size and chemical functionality to the original target molecule. In a number of studies, MIPs have been shown to have binding characteristics similar to those of antibodies and other bioreceptors. A potentially important advantage of MIPs is enhanced stability compared to natural biomolecules. The use of MIPs for the analysis of small molecules is becoming established, but detection of larger biomolecules (e.g., proteins and protein toxins) is more problematic. Here, the formation of the template cavity to conform to the three-dimensional image of the total protein may be difficult (e.g., individual antibodies to proteins respond to one antigenic determinant or epitope).

MIP's may be very suitable sensors for whole cell-sensing, be it of yeast, bacteria, mammalian cells or even viruses. Using a technique called double imprinting, 'plastic' copies of cells or say, antibodies can be produced. In this technique, using an antibody for illustration, the first molecular imprint produces a negative copy of the conformation of the native antibody. This 'plastic' copy serves as a template for another round of molecular imprinting, generating a fully synthetic 'positive' copy of the antibody's structure. The fully synthetic antibody now takes the place of the natural antibody in analyses. Such structures have sometimes shown similar affinity as the native antibody. The same double imprinting technique can be used to generate a positive 'plastic' copy of the whole cell.

A somewhat analogous approach to MIP is to form a self-assembled monolayer (SAM) film (say, an alkane thiol on a gold-coated silicon chip), but to include analyte molecules during the formation of the SAM. Subsequent removal of the analyte molecules leaves 'footprints' of the analyte in the monolayer matrix.

Biomimetic chromic membranes

A specific biomimetic system that has been used for convenient colorimetric sensing of bacterial toxins, bacteria or viruses is the use of cell membrane-mimicking materials ('smart' materials) into which are inserted cell surface receptor residues. These systems use polydiacetylenic membranes (LB or vesicle bilayers) containing either cell surface gangliosides, sialic acid, or carbohydrate residues to detect the presence of toxins such as cholera toxin or influenza virus, the binding event being signaled by a color change (bichromic shift). The specificity of the sensor resides in the ganglioside or sialic acid residues in the polymeric assembly. Ganglioside GM1 is the primary target of cholera toxin on the intestinal cell surface, while gangliosides GT1b are located at the neuromuscular junction and form the target for botulinum toxin. In the case of influenza virus, the sialic acid residues on glycolipids form targets for the viral surface hemagglutinin of the influenza virus, by which pathway the virus is endocytosed into the cell. When these receptor molecules are incorporated into the polydiacetylenic structure, binding of the virus or bacterial toxins apparently induces a distortion of the conjugation plane of the polymer, leading to the color change.

Biomimetic recognition: new approaches

In addition to the new synthetic peptide approaches highlighted above, using a biorecognition element which only consists of the functional core of a receptor has obvious attractive features, such as ease of synthesis, ease of fabrication into a transducing system, etc, yet the requirement, in most cases, for extensive computer simulations to select the appropriate core structure can lead to extensive computer effort. Nevertheless, the effort may well be repaid, if such sensors can demonstrate similar selectivity and sensitivity as the larger receptor from which they are modeled.

Nanosized materials can potentially serve as biomimetic materials. Nano-dimensional structures have obvious advantages for biosensing operations such as biocompatibility, chemical and thermal stability, large surface-to-volume ratios, allowing for immobilization of multiple recognition molecules on their surface, unique physical and chemical properties which facilitate sensitive transduction techniques, and, finally, nanometer size which potentially allows elucidation of discrete subcellular sites where interaction is probed. Biomimetic nanomaterials, at present, comprise mainly nanocomposite structures, in which the core is a nanoparticle or similar structure, and the surface is modified with various receptors which allow biorecognition. For example, positively charged quantum dots (QDs) whose surface structure has been modified with PEG and amino groups, have been used to probe negative surface charge distribution on normal and transformed cells. A novel approach to mapping cell surface glycoconjugates on mammalian cells was to co-embed QDs and magnetic nanoparticles into an organic copolymer nanosphere, which was surface modified with agglutinins (acting as biorecognition elements for cell surface sugar moieties). Thus these composite nanoparticles had functional capability for magnetic separation of cell types, fluorescence tracking of specific biorecognition events (agglutinins binding to sugar moieties), and selective detection of N-acetylglucosamine, galactosamine, and N-acetylgalactosamine on cell surfaces (Xie et al., 2009).

Figure 5 Schematic diagram of typical transduction formats employed in biosensors.

Bio-Amplification as Part of Recognition

Frequently it is desirable to not only specifically recognize the analyte of interest, but to also amplify, in some way, the biorecognition event, as a means of increasing sensitivity of analysis. An obvious example is the ELISA assay, in which the processive activity of an enzyme is used to amplify the recognition of an antibody for an antigenic epitope. There have been many such amplification schemes devised for biosensing applications. Here we highlight a few such techniques which seem to have earned a place in recent analysis schemes. Recent articles have discussed the use of so-called DNazymes, as signal amplification elements in biosensors. DNazymes (or deoxyribozymes) are catalytically functional nucleic acids which can fold into three-dimensional shapes to bind to specific targets. For example, there is a DNzyme structure which can form a G-quadruplex (G-rich motifs) structure which can act, in the presence of hemin, to form a hemin/G-quadruplex complex which has peroxidase activity. Since a variety of substrates are already available for peroxidase reactions, the DNzyme lends itself to ready detection by colorimetry, for example. Analogs of molecular beacon structures have been designed for DNA detection, in which the G-quadruplex sequence is in a caged configuration, and the hybridization of the target sequence to the molecular beacon loop sequence produces a functional DNzyme. Ingenious constructs have been devised, in which an aptamer and a Pre-DNzyme are combined in a hairpin structure. Upon binding of analyte to aptamer, the hairpin opens, and generates the G-quadruplex sequence, which then functions as the DNzyme, upon addition of hemin and peroxidase substrate. Another approach using the same concept was to start with a functioning DNzyme which was in the form of a molecular beacon (but without fluorophore and quencher). Two molecular beacon elements formed the intact G-quadruplex DNzyme. Upon addition of the analyte DNA sequence, the complementary sequences on the molecular beacon surrogates hybridized to the analyte, thus disrupting the DNzyme and producing loss of signal.

Other bio-amplification techniques for signal enhancement have also been used. For example, if molecular beacons are used for recognition of target DNA's, when the beacon unfolds, gold nanoparticles with short oligonucleotide segments complementary to a stem sequence of the beacon can be hybridized to this stem portion. Addition of nucleotides and polymerase can lead to polymerization and release of target DNA, which can recycle to amplify the amount of gold nanoparticles at the transducer surface, thus improving electrochemical detection sensitivity.

Transduction Mechanisms

As described above, the transducer is the portion of the biosensor responsible for converting the biorecognition event into a measurable signal. As shown in Figure 5, it is possible to exploit a change in a number of physical and chemical properties (mass,

temperature, electrical properties, and optical properties) to allow for different transduction formats. The four basic transduction types: electrochemical, piezoelectric, calorimetric, and optical are reviewed here, with emphasis on the advantages and disadvantages to each, and recent advances toward idealizing biosensor performance.

Electrochemical

Electrochemical transduction is one of the most popular transduction formats employed in biosensing applications. One of the main advantages of biosensors which employ electrochemical transduction is the ability to operate in turbid media and often in complex matrices. Another distinct advantage of electrochemical transduction is that the detection components are inexpensive and can be readily miniaturized into portable, low cost devices. In general, electrochemical-based sensing can be divided into three main categories, potentiometric, amperometric, and impedance. Potentiometric sensors typically rely on a change in potential caused by the production of an electroactive species that is measured by an ion selective electrode. For a biosensor system, this change in electroactive species concentration is usually brought about by an enzyme. In an amperometric sensor system, a change in current is directly measured. Electrochemical sensors based on impedance, most commonly utilize impedance spectroscopy since controlled AC electrical stimulus over a range of frequencies is used to detect variations in the sensor surface properties (i.e., charge transfer and capacitance at the interface layer). In this way, the resistance to flow of an alternating current is measured as voltage/current. For example, metabolic changes (e.g., growth and metabolism) have been shown to correspond to an increase or decrease in impedance. Some of the many variations of potentiometric, amperometric, and impedance biosensors that provide for improved biosensor performance include field effect transistors (FETs) and electrochemiluminescence (ECL).

Field effect transistors

Many researchers have recently looked to FETs as a means to miniaturize potentiometric sensors, while providing increased sensitivity due to minimal circuitry. A particularly promising FET advance includes the light addressable potentiometric sensor, or LAPS, which consists of an n-type silicon semiconductor-based sensor and an insulating layer that maintains contact with the biological solution. Detection of potential changes occurring at this silicon interface are monitored as differences in charge distribution between the insulator surface and the FET. To accomplish this, alternating photocurrents generated by a light-emitting diode are utilized, so that changes in potential can be transduced into voltage per time differentials. Successful application of the LAPS has been demonstrated with commercially available systems, for the detection of biological threats of interest to defense applications, as well as foodborne pathogen threats of concern to food safety applications.

Electrochemiluminescence

ECL combines the advantages of chemiluminescence (high sensitivity and low background) with electrochemical transduction. ECL utilizes a controlled voltage potential at the surface of an electrode to power a luminescent redox reaction. The redox reaction most commonly employs a ruthenium (II) trisbipyridal chelate coupled with a tripropyl amine, although recent studies have demonstrated success with other fluorophore species.

Mass

Biosensors that detect the change in mass due to target and biorecognition element interactions predominately rely on piezoelectric transduction. Piezoelectric transduction relies on an electrical charge produced by mechanical stress, which is correlated to a biorecognition binding event causing a change in the mass on the piezoelectric device. The main advantage to the piezoelectric transduction (i.e., mass sensor) approach includes the ability to perform label-free measurements of the binding events, including real-time analysis of binding kinetics.

Bulk wave

The most commonly employed transducer is the quartz crystal microbalance (QCM), which relies on a bulk wave effect, illustrated in Figure 6. A QCM device consists of a quartz disk that is plated with electrodes. Upon introduction of an oscillating electric field, an acoustic wave propagates across the device. The change in mass associated with bioreceptor–target interactions causes a decrease in the oscillation frequency that is directly proportional to the amount of target. This transduction format can be coupled to a wide variety of bioreceptors (e.g., antibody, aptamer, and imprinted polymer), provided that the mass change is large enough to produce a measurable change in signal. Not surprisingly, QCM transduction is not capable of small molecule detection directly, and usually requires some sort of signal amplification to be employed.

Surface acoustic wave

Changes in the overall mass of the biomolecular system due to association of the bioreceptor with the target analyte can be measured using alternative piezoelectric transducer devices that offer some advantages over bulk wave sensing. For example, surface acoustic wave (SAW) devices exhibit increased sensitivity compared to bulk wave devices and transmit along a single crystal face, where the electrodes are located on the same side of the crystal and the transducer acts as both a transmitter and a receiver. SAW devices can directly sense changes in mass due to binding interactions between the immobilized bioreceptor and target analytes and exhibit increased sensitivity compared to bulk wave devices. However, the acoustic wave is significantly dampened in biological

Figure 6 Schematic diagram of a biosensor based on piezoelectric/acoustic wave transduction.

solutions, limiting its utility for biosensing applications. Some improvements using dual channel devices, and special coated electrode systems allowing for noncontact SAW devices, which can function in biological solution interfaces have been produced. However, reliable biosensor application incorporating these devices is still under pursuit, as improvements in sensitivity are still required for specific microbial analyses.

Micro- and nanomechanical devices

Micro- and nanomechanical cantilevers can be manufactured through silicon fabrication techniques developed in the electronics industry. Under ambient temperature conditions, the cantilever devices naturally oscillate, and this resonant frequency can be monitored (Figure 7). Through modifications with bioreceptors, target interactions can be monitored as changes in mass, and hence the resonant frequencies, upon binding. Obvious advantages of this form of transduction include low cost and mass production. However, practical applications to biosensing are limited due to oscillation dampening in liquid solutions, compared to air- and vacuum-packed cantilever systems. To address this limitation, there have been recent advances toward incorporating hollow channels inside the microcantilever in order to immobilize the bioreceptors internal to the device. In other words, high resonant efficiencies obtained through vacuum packaging can be maintained, while specific mass changes can be monitored by flowing the sample through the inside of the device. Further signal enhancements can be obtained through use of nanoparticle and magnetic bead amplification to cause larger frequency shifts, and overall a more sensitive analysis.

Figure 7 Schematic diagram of a microcantilever-based biosensor.

Nanomechanical Transduction Techniques

Although the fundamental principles involved (e.g., mass sensing) already are in use in micro- or meso-scale (see discussion in text above), the development of nanoscale fabrication of materials has opened paths to novel sensing devices. Only recently has the sensing of mechanical processes (e.g., deformation, stretching, bending) in biology systems begun to receive some wide-spread attention. For example, the 'lock and Key' analogy of antibody/antigen interaction implies a certain rigidity while, in fact, actual conformations may be fluid and only attain a more-or-less fixed state upon the binding event occurring. When proteins (for instance) bind to membranes, the chemical interposition within the membrane translates into mechanical membrane bending, so that mechanical stress at the membrane may be important in multiple biological and pathological processes. The mechanical properties of cells themselves may provide valuable insight into differences between malignant and normal cells: transformed cells deform more (stretch) than non-malignant cells. Also, some viruses show changes in elasticity as the viral particles mature. The tremendous advantage of nanoscale devices to analyze such processes is that the sensors themselves are not much larger than the molecules which are being probed, so that even small changes translate into detectable events in the sensor. Mechanical sensors fabricated with nanosized moving parts whose vibration and deformation are sensitively altered by molecular adsorption have great potential for mechanical sensing. Thus, nanomechanical systems which use the same principle as quartz crystal microbalances can resolve masses verging on the scale of single atoms. Biological interactions such as nucleic acid hybridizations, protein-carbohydrate interactions, conformational changes in viruses upon viral packaging, are all amenable to nanomechanical sensing.

Flexural-plate wave

A flexural-plate wave (FPW) transducer contains a thin membrane that can propagate a SAW. The FPW is in contact with a thin film of liquid that vibrates with the membrane and hence the change in mass of a vibrating element can be detected to indicate biological interactions. This technique is not very sensitive, but similar to SAW devices can provide for real-time analyses.

Calorimetric

Calorimetric sensors utilize thermometric probes, such as thermistors, resistance temperature devices, and thermocouples, to monitor changes in temperature due to exothermic chemical reactions. Many biological reactions are exothermic (e.g., enzyme reactions), and hence calorimetric detection allows for a near universal transduction format. One key disadvantage of this approach is that environmental temperature fluctuations must be shielded from the sensor system. Traditionally calorimetric biosensors have been large and bulky, although advances in silicon microfabrication technologies and microfluidics have allowed for miniaturization and improved performance.

Optical

Due to a number of advantages, optical transduction is one of the most widely used biosensor transduction formats. For example, optical transduction can be very rapid where the limiting factor for the speed of detection is often a diffusion-limited process of the biomolecular recognition event, rather than the optical transducer. Another advantage of optical transduction is the interferences that can hinder electrochemical transduction measurements such as voltage surges, harmonic induction, corrosion of electrode elements, and radio frequency interferences are not present. Some of the disadvantages of using optical transduction formats include: detection challenges when analyzing turbid samples, and the cost associated with detection system components. A wide variety of optical transduction formats have been employed, where changes of the interaction of light with the biomolecular system is used to produce a measurable signal. These changes can be based on differences in refractive index, production of chemiluminescent reaction products, fluorescence emission, fluorescence quenching, radiative and nonradiative energy transfer, temporal changes in optical emission properties, scattering techniques as well as other optical effects. These effects can be monitored using a variety of optical platforms including total internal reflectance and evanescent wave technologies, interferometric, resonant cavities, biochip devices, and so on. The following paragraphs review the most common as well as most popular emerging optical transduction formats: fluorescence, interferometric, chemiluminescence, surface plasmon resonance (SPR), and surface enhanced Raman spectroscopy.

Fluorescence

Fluorescence is the most popular form of optical transduction due to the high sensitivity that is fundamental to this type of optical process. Another advantage of fluorescence-based methods is that they generally do not have the interference issues that SPR and other refractive index-based methods possess. However, in most cases, the intrinsic sample fluorescence is not sufficient for analysis, and a fluorogenic reporter is used to label an affinity reagent to create a bioreporter. By monitoring the intensity of the fluorogenic reporter, it is possible to determine the presence and concentration of the target analytes, as illustrated in the bioassay techniques section described previously. It is also possible to monitor shifts in the wavelength of the fluorophore reporter, as well as energy transfer phenomena, and time dependence of the fluorescence emission, all of which can be related to binding interactions depending on the assay employed. The distinguishing features between fluorescence-based biosensors, besides the above mentioned properties that can be monitored, include the optical detection format used. For example, it is possible to utilize fiber optic probes, often termed optrodes, to immobilize bioreceptors at the tip of the fiber, and use total internal reflectance properties of the

fiber to transmit excited and emitted light. Total internal reflectance can also be employed in an evanescent wave format, where a residual amount of (evanescent) light at the reflectance point that escapes is used to excite immobilized bioreceptors only in close proximity to the surface, rather than in bulk solution. This format allows for controlled excitation, and can allow for minimal fluorescence background. However, a key disadvantage is the lack of evanescent excitation power, and sometimes poor coupling of the emission when using similar collection geometries. Fluorescence detection can be used with a wide variety of detection formats. For example, it is routinely coupled with flow cytometry and microfluidic platforms or imaging array systems such as biochips which utilize spatial patterning of biological recognition elements to match fluorescence location to target species.

Interferometry

Interferometers can measure biomolecular interactions that take place at a surface within an evanescent field that causes a refractive index change and a corresponding change in the phase of the propagating light. For example, a Mach-Zehnder interferometer-type of sensor can be constructed in which an optical waveguide is split into two arms of equal length and is recombined before the detector. One arm is a reference arm, which does not experience refractive index changes, while the other is the sensing arm. In the absence of analyte, light from both arms is in phase as it reaches the sensor. If analyte is bound to bioreceptors on the sensing arm, the local refractive index of the evanescent wave is altered, producing a phase shift, which results in destructive interference at the detector, resulting in an output power loss. Studies have indicated that 10^{-5} to 10^{-7} changes in refractive index units can be detected with these sensors (Washburn and Bailey, 2011). Although this approach has been in existence for quite some time, it is primarily a laboratory technique since it is not a very robust biosensor technology, and suffers from significant false-positive results.

One potential difficulty with interferometric sensing is that the length of the optical wavepath necessary to produce interference can be on the order of a centimeter, which is large compared to many other optical detection devices. A possible design for multiplexing (chip-integrated Young interferometer) is to project the light output from the optical waveguides onto a CCD device, which allows analysis of the interference patterns, which could be then extended to several different waveguides analyzing different analyte species.

Nevertheless, potentially very powerful biosensing technologies based upon evanescent waves and changes in refractive index are currently being explored. See below for in-depth discussions of these concepts (Optical Resonators, Waveguide Mode Sensors). Other procedures can be used to increase sensitivity of optical techniques employing refractive index changes as signaling events. The use of enzymes to amplify output signals of sensors is a standard technique in assays like ELISA. It is also possible to apply the same strategy for interferometric sensors. For example, using an enzyme coupled to an antibody, and with a substrate which produced a colored product in solution, it was possible to amplify the index change in an interferometric optical sensor, since the colored enzymatic product generated a larger change in index than without enzyme amplification.

Chemiluminescence

Chemiluminescence is one type of optical sensor technology which relies on a series of chemical reactions, usually employing oxidation of a luminol reactant, to produce a reaction product that gives off characteristic light. The intensity of this light is correlated to a sample target of interest, by coupling some of the reaction products to biorecognition elements, to serve as chemiluminescent reporters. The advantage of chemiluminescent transduction includes very low optical background. Theoretically the background in the absence of analyte for a chemiluminescent biosensor should be very low or non-existent, leading to a very sensitive (high signal-to-background) measurement but practically, non-specific interactions commonly occur, resulting in some low to very low level of chemiluminescence even in the absence of analyte. The reaction usually employs signal amplification and bioassays with multiple washing and labeling steps, which leads to a somewhat time-consuming analysis.

Surface plasmon resonance (SPR)

SPR is a phenomenon that can exist at the interface between a metal and a dielectric material such as air or water. A surface plasmon (commonly excited by optical radiation) of the electrons at the surface of the metal results in an associated surface bound and evanescent electromagnetic wave of optical frequency. This evanescent wave has a maximal intensity at the interface and decays exponentially with distance away from the interface. In SPR-based biosensing, changes at the interface, that is, biological recognition element and analyte binding, causes changes in the local refractive index which in turn causes changes in the resonance excitation of the surface plasmon.

SPR is a form of reflectance spectroscopy, where change in a SPR that occurs during optical illumination of a metal surface is harnessed to detect biomolecular interactions. A schematic diagram illustrating a basic SPR chip platform is illustrated in Figure 8. The SPR chip consists of a prism with a thin gold film upon which the bioreceptors are immobilized. Light is totally internally reflected from the prism face coated with metal and the changes in reflectivity measured. Surface plasmons are excited at a specific incident angle and result in a massive reduction in reflectivity at that angle. Changes in the refractive index at the interface results in a change of the optimal angle required for excitation.

Any change in the optical properties of the medium in contact with the immobilized layer will cause changes in the characteristics of the surface Plasmon wave. Specifically, these changes can be measured as changes in wavelength, intensity, phase, or angle of incidence. SPR techniques are widely popular in contemporary biosensor development because it is a surface-sensitive technique that can measure real-time interactions between unlabeled species.

Although SPR is a simple technique with a number of advantages, it is not the most sensitive. However, one variation of SPR includes a resonant mirror format which utilizes a series of polarizing filters to block light that is internally reflected. At a particular

Figure 8 Schematic diagram of a biosensor utilizing surface plasmon resonance (SPR) transduction.

incident resonant angle, the light is diverted through a spacer layer that has a low refractive index, into a higher refractive index guide so that the signal peak appears on a dark background. Despite these advances, one of the primary limitations of SPR-based biosensors is that anything which alters the refractive index at the sensing surface will interfere with the analysis including nonhomogenous (complex) sample matrices, and nonspecific binding interactions.

Surface enhanced Raman spectroscopy

Another type of plasmonic spectroscopy that is gaining popularity in biosensing applications is surface enhanced Raman spectroscopy (SERS). SERS is an enhanced form of Raman spectroscopy, where a nano-roughened metal surface is used to enhance the scattered Raman signal. The SERS enhancement is thought to be the result of a combination of intense localized fields arising from SPR in metallic nanostructures and chemical effects.

Advantages of this approach include the ability to obtain a spectroscopic fingerprint, similar to infrared absorption spectroscopy, while being relatively interference-free from water. Also, since SERS is an enhanced technique, it can be used to see very low concentrations of even biological materials, as evidenced by recent interest in a variety of immuno-SERS methods under development. The difficulties often encountered with SERS biosensors, primarily stem from signal reproducibility challenges, which are directly tied to the reproducibility of nanostructured SERS substrate fabrication. Of the transduction methods covered in this article, SERS is one of the least established for biosensor development but shows much promise for continued development.

A review of recent literature finds SERS is increasingly employed in biomedical applications. A variety of factors are responsible for this surge in interest. Among these factors are the facts that SERS can be used to detect analytes in complex mixtures directly, without separation steps, that it can sample non-invasively from tissues and cells, that it potentially can sensitively detect small changes in structures of macromolecules, that it has high spatial resolution, and that it can be readily multiplexed, thus allowing analysis of multiple analytes simultaneously. Further advantages include a remarkable freedom from interference in SERS measurements due to unexpected species which might appear in complex biological samples, and the ability to suppress fluorescent backgrounds produced by common biological species by carrying out SERS analysis in the near IR. The reduction in background noise of complex biosamples possible using SERS is one of the most attractive aspects of this analytical technique. A complete description of the foundational theory behind the SERS process is beyond the scope of this review. In brief, SERS depends primarily upon electromagnetic effects on nanostructured materials. Surface charges (also called surface plasmons) on a metal surface are delocalized and flow freely and can be resonantly excited by an oscillating external electric field (i.e., a laser beam). If incident light frequency matches the natural oscillating frequency of the surface plasmons, strong electric fields can arise. Thus the fundamental process associated with SERS is the production of an enhanced electromagnetic near field at the surface of metallic nanostructures when localized surface plasmon modes are excited by laser irradiation, and this localized electromagnetic field can interact with the molecules on or near the nanostructure surface, thereby enhancing their scattering properties. It is generally accepted that the aforementioned electromagnetic enhancement is the dominating process for SERS, although chemical (i.e., charge-transfer) SERS enhancement also contributes to the overall SERS enhancement. The sensitivity associated with SERS comes from interaction of the electromagnetic field produced by the surface plasmons with the analyte, which must be in very close contact with a plasmonic surface, resulting in sensitivities even down to single molecule detection, in contrast to the inherently insensitive Raman scattering spectroscopy. It should be noted that there is another effect, very similar to SERS, which is surface enhanced resonance Raman scattering (SERRS). In this latter case, when the molecule to be detected has a chromophore which is close in energy to the frequency of the excitation used to excite the surface plasmon and generate SERS, enhancement of the scattering occurs both because of

plasmon resonance (SERS) and molecular resonance, resulting in very intense scattering and producing very large enhancement factors (sometimes in the range of 10^{13} to 10^{15}).

Much has already been written about the importance of the structural details of the plasmonic surface, and the underlying theory has also been discussed. In this brief review, we cover only recent advances of relevance to biomedical sensing. Practically, gold and silver are the two plasmonic materials of choice for SERS at present. The recent development of the field of nanomaterials has provided a rich resource for potentially novel and effective SERS substrates. Among the most important are various nanoparticle (NP) structures. It has been noted that NP's with corners such as nanocubes or the ends of nanorods or the sharp points of nanostars, nanoflowers or nanopopcorn can strongly focus the electromagnetic field generated by the laser interacting with metallic surface plasmons at such points, producing strong SERS enhancement. Also, formation of so-called 'hot spots', which are specific gaps between nanoparticles where the electromagnetic field is very high due to coupling between plasmon resonances of the NP's, can probably be controlled by engineering design in nanostructures, rather than leaving formation of such interactions to chance as would occur in colloidal NP suspensions. In fact, structures such as nano-crescent moons or nano-plasmonic split rings have been produced to utilize 'hot spots' associated with these structures.

One of the requirements for effective SERS enhancement is very close apposition of the analyte to the metallic surface. Various techniques have been devised to provide a more-or-less universal SERS detection scheme which can be applied to wide ranges of analytes. Methodologies involving molecular traps and cages have been used; one example is the use of a temperature responsive pNIPAM gel coating gold NP's to trap small molecules such as (1-naphthol), which are brought into close proximity to the gold NP surface by raising the temperature, thus collapsing the gel and forcing the analyte into close contact with the NP surface. A variety of techniques for trapping/capping various analyte molecules on NP's are discussed in [Alvarez-Puebla and Liz-Marzan \(2012\)](#). On the other hand, various molecules, such as antibodies, can be immobilized onto NP surfaces, thus providing specificity for capture of the desired analyte. Actual detection of the analyte can be either by direct or indirect techniques. In the direct method, the analyte is detected by the SERS spectral fingerprint of the analyte molecule, and this fingerprint is generally unique to each substance, due to differences in chemical structure. Both large macromolecular structures (and even microorganisms and eukaryotic cells) and small molecules are theoretically amenable to direct sensing. Many molecules, however, have a low SERS cross-section and so the detection sensitivity for such molecules is poor. Antibody capture of an antigenic analyte can also be considered direct detection, if the SERS spectrum of the resulting antibody/antigen complex is detected. In such cases, it is necessary to subtract the antibody SERS spectrum from the composite spectrum. Analogous detection by direct spectroscopic fingerprinting of specific DNA sequences can take place following hybridization of the target DNA to DNA immobilized on NP's. In indirect detection SERS techniques, a strongly SERS-active substance (i.e., SERS dye) is incorporated into NP's (the particles may also have capture ligands attached), and the resulting NP's basically serve as barcodes for detection of the analyte. In practical terms, it has been found necessary to coat the SERS active NP with a protective shell (usually silica), which also provides a convenient surface for deposition or attachment of various biomolecules which could be used for bio-specific interactions with the analyte. These SERS barcoded NP's could be used for biochip-type detection scenarios or even inside living cells for biological function/imaging studies.

The requirement for metallic surface plasmons for SERS has also resulted in development of so-called nanopatterned metallic platforms, which are surfaces with nanostructured features (usually constructed from nanospheres, nanorods, etc) overlaid with a thin metallic film. These platforms have the great advantage of stability against aggregation-induced irreproducibility (a problem with metal colloids) in SERS spectra, and can be used either for direct or indirect biosensing of various analytes. Biosensing microarrays can be constructed using the nanopatterned metallic platform concept, and using variously labeled and functionalized probes. Thus, one approach used was to employ single-walled carbon nanotubes (SWNT), constructed with either C^{12} or C^{13} and attaching antibodies specific for various proteins onto the SWNT surface. The SWNT become SERS-based sensors which can bind to spatially localized protein targets on the nanopatterned metallic surface. Sensitivities of the order of fM were obtained with this system ([Kho et al., 2011](#)).

Some investigators have developed SERS analogs of the molecular beacon concept. In this case, target DNA (or RNA) sequences are detected with a stem-loop structure, which has a SERS-active dye on one end of the stem and a NP on the other end of the stem in close apposition. Thus the SERS signal is strong when the stem-loop structure is intact, but when the target DNA hybridizes to the complementary sequence on the loop, loss of the SERS signal occurs when the stem-loop structure unfolds. Detection of biomolecules using SERS has encompassed a wide variety of targets including lipids, nucleic acids, proteins, metabolites, sugars, bacteria and eukaryotic cells. Detection limits usually attainable range from fM to nM, but, greater sensitivities are reported in certain experimental set-ups. One particularly attractive area for future research efforts in SERS might involve the well-known ability of SERS to respond sensitively to changes in chemical structure. A practical example could be placing a SERS-active tag at the proximity of a binding site on one member of an interacting pair, such as tagging the antigen-binding site of an antibody, and then using the SERS tag to report on changes associated with the binding event. This has potentially much wider applicability than just antigen-antibody interactions ([Kho et al., 2011](#)).

Intracellular biosensing using the SERS technique has great potential, but relatively few studies have so far been done. Since the SERS technique depends upon metallic surfaces and the resulting plasmon resonances, the usual procedure is to use NP's tagged with SERS-active dyes for intracellular sensing. Part of the problem is then the difficulty in directing NP's to the appropriate intracellular compartments. Another issue is the strong tendency for NP aggregation in the highly complex intracellular environment. It should be recognized that NP's are much larger than typical molecular fluorophores, so their intracellular behavior would be expected to be much different. Intracellular delivery of NP's by many common techniques results in most NP's residing in vesicles inside the cell. Thus various techniques, such as microinjection or cell penetration by a nanofiber, have been used to 'force' the SERS

sensor into desired intracellular locations. One approach to introduce NP's into the specific intracellular compartments is the incorporation of, for example, nuclear targeting peptides such as the HIV-1 TAT on the NP surface. Other procedures can also be used to overcome aggregation problems and improve targeting. Using a stabilizing agent (i.e., protein, like BSA, silica or polyethylene glycol) to coat the NP's using appropriate chemical procedures will protect the NP's, partially prevent aggregation, and these coatings have the further advantage that biomolecules such as antibodies can be appended to the surface coat, resulting in NP's targeted to specific intracellular sites (Yuan et al., 2013).

Optical Resonators: Whispering Gallery Mode Sensors, Photonic Crystals

Whispering Gallery Mode (WGM) biosensors and other optical resonant microcavity-based sensors are adding a whole new class of sensing devices to the armamentarium of analytical techniques with biological applications. Potential advantages of these devices are that they are able to operate without the need for labels, can sense in real-time, and can display extreme sensitivity, even down to single molecule or single virion detection. Excellent recent reviews of these sensors as applied to chemical and biomolecular analysis can be found in Luchansky and Bailey (2012) and Yoshie et al. (2011). The optical theory describing the functioning of WGM sensors can become rather involved, but the basics can be described in a qualitative manner. When light propagates through an optical fiber, and is totally confined (total internal reflectance), then an evanescent wave is induced in the medium surrounding the fiber, and this wave extends ~ 100 – 200 nm beyond the surface of the fiber. If molecules are now attached to the fiber's surface, the evanescent wave can interact with them, resulting in an increase in the path length and number of wavelengths of light traveling through the guide. Unfortunately, this effect is so weak that trying to resolve the resulting change in wavelength by interferometry is essentially futile. Now, however, if the photons, guided by total internal reflectance, travel around a silica (for example) sphere (say of radius $100\text{ }\mu\text{m}$), then each photon is recirculated many times. If the wavelength of the light is tuned so that the light is in phase after each revolution around the sphere (i.e., integral number of waves in one revolution of the sphere's circumference), then the light drives itself in a resonant manner. Practically, a tapered fiber-optic waveguide is attached to a tunable laser and is referred to as the driving fiber. This fiber is arranged in close apposition (for evanescent coupling) to a silica sphere which is formed on the end of a tapered glass fiber. Tuning the laser to a wavelength such that the evanescent wave circles the sphere an integral wavelength number of times results in a dip in light intensity at the other end of the driving fiber, where a photodetector is located. This is the resonance wavelength. Now, if molecules are attached to the surface of the sphere (say, by reaction with receptors previously bound to the surface), then the photon path length increases, and the light is perturbed out of resonance. Tuning the laser to return the sphere to the resonant state will result in an increase in the wavelength of the light to achieve resonance. The shift in the wavelength of the resonant light is the event detected, but this shift cannot be observed unless the resonance linewidths are very narrow. The sensitivity of the WGM sensor is directly related to the spectral resonance linewidth. Resonance theory indicates that the sensitivity of this resonance shift is proportional to the number of times photons recirculate around the sphere, which is several thousand to hundreds of thousands for devices so-far used.

One can also think of the sensing aspect of WGM resonators as follows. If a resonance dip is detected when the wavelength of the orbiting light is such that integral multiples of this wavelength match the microsphere circumference, this means that power is being extracted from the fiber, which results in loss of light intensity at the detector end of the fiber. Even a very thin coating of molecules adhered to the surface of the microsphere will change the radius or orbital refractive index of the sphere, and so the resonant wavelength must change. Practically, achieving requisite sensitivity depends on the Quality (Q) factor of the resonator. For example, Vollmer and Arnold (2008) discuss a hypothetical WGM sensor with a Quality factor of 2×10^6 , and estimate that a shift in wavelength of 6 fm (femtometer) can be detected. They indicate that only a very thin layer of bound material is necessary to achieve this shift. In fact, further calculations indicate that a wavelength shift of 6 fm is equivalent to a change in radius of the microsphere of ~ 0.5 pm and since the size of a typical protein is 1–10 nm, this suggests only a small fraction of a monolayer should be detectable.

The quality (Q) factor of a device using this sensing scheme can be thought of as a measure of the resonant photon lifetime within the optical structure, so Q is directly related to the number of times a photon is recirculated and reacts with the analyte. The evanescent field on the exterior of the optical waveguide, associated with light which is confined by total internal reflection, interacts with molecules in close proximity to the surface of the sensor. High Q optical sensors produce light resonances at very specific wavelengths, and these resonances change as the RI at the sensor surface changes upon changing surface properties (i.e., attachment of analyte to surface). Higher Q values are associated with narrower resonant peaks; narrower resonant peaks translate into sensors with greater sensitivity, because narrower resonance peaks can be resolved better, even if the resonance shift is very slight.

Vollmer et al. (2008) carried out studies of WGM sensors, first using polystyrene (PS) microspheres and then testing detection of Influenza A virus particles. Successful adsorption of individual PS microspheres of 250 nm radius to a silica microsphere of ~ 45 micron radius was detected by definite steps of resonance shift which could be clearly seen above background cavity noise. These experiments allowed studies of the dependence of the wavelength shift upon the microsphere radius. Detection of individual Influenza A virions was attempted using a laser wavelength of 763 nm and a microsphere of radius 39 microns. Adsorption of individual virus particles was observed as a step function of shifts of resonance wavelengths, above background noise. The radius of Influenza A virion particles as calculated from equations associated with the WGM studies was 47 nm, while the size from SEM micrographs was 45–55 nm.

A variety of optical configurations have been devised to take advantage of the WGM concept. For example, microrings microdiscs and microtoroids have been used, in which the driving fiber is closely apposed to either a ring, disc, or toroidal surface, while yet

another configuration is a tapered optical fiber which is apposed perpendicularly to a cylinder, so that the light circulates around the surface of the cylinder (and the interior of the cylinder could be a microfluidic channel, for example). Microring resonators and microdisk resonators have the advantage of being able to be fabricated on planar substrates, and so have the potential to be manufactured by standard chip fabrication techniques. Current microfabrication techniques are difficult to standardize in constructing these devices. Another significant factor is the requirement for precise alignment of the sensing device with the optical fiber to achieve WGM excitation. This is particularly of concern for the microtoroidal configuration, but is true for other configurations as well. In fact, fluidic flow may easily disrupt these critical alignment factors for WGM resonance, so liquid-based detection of analytes can present problems. Q factors ranging from $\sim 10^4$ to $\sim 10^8$ or 10^9 have been measured with various microresonators of shapes described above (Luchansky and Bailey, 2012).

Armani et al. (2007) used a silica-based microtoroidal resonator which uses the WGM sensing technology, and which had a remarkable Q factor of 10^8 , as opposed to Q factors of $\sim 10^6$ for microsphere-based sensors. The higher Q factor of the microtoroidal WGM sensor as opposed to the microsphere WGM sensor is apparently due to the planar nature of the microtoroid. A typical diameter of the microtoroid fabricated was 80 microns. With a Q factor of 10^8 , a single target molecule on the microtoroidal surface is sampled more than 100,000 times by the input light, thus producing incredible sensing amplification. Studies involving detection of Interleukin 2 (IL-2), using microtoroidal cavities modified with antibodies to IL-2, indicated a working range of an astonishing 10^{12} in concentrations able to be detected, although the response was not linear over this whole range. Further studies with very dilute solutions of IL-2 showed step function increases in resonance shift, indicating single molecule binding events such as was detected in the work of Vollmer et al. (2008). A variety of experiments were carried out to verify the single-molecule nature of these events.

One way in which to increase sensitivity and specificity using WGM sensors such as those described above, is to take advantage of so-called 'sandwich' assay formats. Luchansky and Bailey (2012) give several examples of such techniques in their review article, such as using a secondary antibody specific for a protein analyte. Thus one antibody captures the analyte on the sensor surface, while the second antibody provides another specific recognition element, while at the same time further increasing the RI change which the sensor can detect. Another concept to further enhance sensitivity is to use very large tags, such as microbeads or nanoparticles, to produce large changes in RI when reagents tagged with such particles binding to the sensor surface, thus providing greater shifts in resonance peaks. In fact, a variety of biological techniques are potentially applicable to such WGM sensors, like using various shapes of nanoparticles, or rolling circle amplification or enzymatic amplification.

Photonic crystals (PC) are essentially made up of spatially periodic constructs of dielectric materials with different refractive index properties, and so confine light due to this periodic structure. For PC sensors, light is back-reflected at only certain resonance wavelengths, which are not allowed to propagate through the periodic dielectric structure (the range of wavelengths which are not allowed to propagate are called the photonic bandgap). The photonic bandgap can be tuned by either varying the RI contrast of the dielectric materials making up the PC or by altering the periodicity of the structure. Frequently, the periodic structure consists of a series of nanoholes in the dielectric surface. Generally, a defect (acting as a resonance cavity) is introduced somewhere in the periodic structure. Certain frequencies of light become confined in the defect structures, thus resulting in high optical field densities around the defect. The RI at the defect site determines the resonant frequency coupled into the crystal. If biomolecules are immobilized in the defect microcavity, changes in the RI occur, with resulting changes in the resonance frequency. The fundamental sensing paradigm is similar to the sensors described above, where changes in RI are detected. Moderately high Q factors can be attained using these devices, so great sensitivity is possible. For instance, less than 10 fg of BSA have been detected using a PC. It has been reported, however, that the sensitivity of detection for PC's is at least 1 order of magnitude less than for resonant microcavity or interferometric sensors (Washburn and Bailey, 2011).

Waveguide Mode Sensors

There are other approaches which make use of evanescent waves detecting interaction of analytes and biorecognition elements at surfaces, by changes in RI. In one approach, denoted as optical waveguide light-mode spectroscopy (OWLS), a thin-film, single mode planar waveguide (denoted as optical grating coupler sensor chip) is fabricated, with a grating etched into the waveguide at the point of optical input. The waveguide layer is sandwiched between two other layers. Light is launched into the waveguide at an incident angle such that it propagates by total internal reflection. An evanescent wave is generated which penetrates into the upper layer (assuming light is launched from the bottom) which has ligands for binding the analyte of interest. Binding of analyte on the surface of the sensor produces a change in the RI, which affects the evanescent wave. This, in turn, generates a change in the angle of incidence at which light is maximally coupled into the waveguide. This change in incident light angle is what is monitored. Other, similar sensors are called wavelength-interrogated optical sensors. In these sensors, wavelength changes are measured as the output signal, rather than incidence angle. Gopinath et al. (2012) discuss using aptamers as biorecognition elements on waveguide mode sensors. Of particular interest are two experimental procedures they use to increase sensitivity. One involves the perforation of the waveguide surface with nanoholes (e.g., 50 nm diameter) to increase molecular accumulation of ligands on the waveguide surface. Size of the nanoporations is critical however, as too large a size increases scattering of incident light and interference, decreasing sensitivity. Another technique to increase sensitivity is to attach a chromophore to, say, the target molecules. If proteins are targeted, using aptamers which bind a specific protein, then one easy technique is to add Coomassie Brilliant Blue (a non-specific protein stain) to the analyte solution. Proteins captured by the aptamer will also have the dye attached to them. This dye-coupled protein produces a much larger detection signal (i.e., resonant peak) than in the absence of dye.

Applications of Biosensors

Bacterial Biosensors for Environmental Monitoring

Whole cell bioreporters which respond to certain pollutants/toxicological conditions are beginning to find applications in environmental sensing. Applications range from detection of contaminants, measurement of pollutant toxicity, monitoring of genetically engineered bacteria released into the environment, and even uses for detection of stresses such as ionizing radiation and oxidative damage. In general, such whole cell sensors should not be called biosensors unless the cells are integrated somehow into a stand-alone sensing/transduction/readout system. Some whole cell sensors use genetically engineered bacteria into which a *lux* gene construct (coding for an active luciferase) under the control of an inducible promoter is introduced. The general sensing strategy is to put the luciferase construct under control of a promoter that recognizes the analyte of interest although in some cases, the bioreporter organism can be engineered to respond to many analytes (broad specificity) by using a heat shock promoter or other general stress response mechanism, fused to the *lux* cassette.

For example, the seminal work in this arena describes a naphthalene biosensor organism (genetically engineered *Pseudomonas fluorescens*) that detected the bioavailability of naphthalene (serving as a surrogate for polyaromatic hydrocarbons) and salicylate in contaminated soil by induction of the *lux* reporter, and subsequent bioluminescence as a result of expression of the reporter gene. The naphthalene biosensor described above is an example of a catabolic bioreporter. Catabolic bioreporters produce luminescence only in the presence of a specific contaminant, since the *lux* genes are linked to a degradation pathway promoter. Metabolic bioreporters, on the other hand, have reporter genes downstream of a strong constitutive promoter, and thus luminescence is directly affected by toxic agents that interfere with metabolism. These concepts have been subsequently used to develop a variety of bioreporter organisms. Other investigators have used genetically engineered bacteria in which the green fluorescent protein (GFP), (or derivatives thereof), initially derived from the jellyfish *Aequorea Victoria* functions as a bioreporter in the same manner as the *lux* gene. Some arguments have been advanced that the expression of bioluminescence is a more direct bioreporter than GFP expression, since the expression of GFP is only detected upon excitation with the correct wavelength of light. However, in practical terms, bioluminescence must be quantified by some sort of photodetector/luminometer, so the difference between that and a fluorescence excitation/emission detection system seems minimal. Beta-galactosidase enzymes have also been used as biomarkers. Others have used naturally luminescent bacteria (i.e., *Vibrio fischeri*) as bioreporter organisms, since toxic compounds can disturb metabolic processes, thus causing a reduction in their bioluminescence. Microbial biosensors have been developed to assay biological oxygen demand (BOD), a value related to total content of organic materials in wastewater. These sensors often measure BOD by evaluating the rate at which microbial cells deplete oxygen. It is not possible to provide a comprehensive list of whole cell sensor applications in this article. Very seldom are these bioreporter organisms integrated into a complete sensing package where a microculture environment, integrated luminometer or fluorometer, and light-tight enclosure can produce a true biosensor device.

Food Biosensing

Some of the factors of interest in regard to analysis of foods include monitoring nutritional parameters, food additives, contaminants, microbial contamination, shelf life assessment and factors such as smell and odor. Many of the aforementioned factors have to do with quality of the food, while others reflect directly on food safety. There are obvious overlaps between food quality and food safety. The assessment of food quality can be subjective, as factors such as appearance, taste, smell, and texture may enter into the overall evaluation. Sensor technologies that measure specific parameters such as sugar content and composition, total titratable acidity (e.g., for fruit), specific chemicals such as glucose, sucrose, lactate, alcohol, glutamate, and ascorbic acid provide more objective means of evaluating food quality and freshness or spoilage. Also, quantitative detection of contaminants of food such as growth hormones fed to animals, antibiotics and pesticides is important. Finally, there is the issue of pathogen and/or pathogen toxin contamination of food. This last is of great concern because of the potential for outbreaks of foodborne illnesses, such as are seen periodically. Fatalities can result from such exposures, and recent outbreaks have generated much media interest.

There is a clear role for biosensors in many areas relating to food quality and food safety. The space limitations of this article will not permit consideration of all aspects, and so the authors have chosen to focus on pathogen detection in food products. Recent reviews of statistics regarding pathogen testing (all types of tests including biosensors) in the food industry prove interesting in regard to future biosensor development. For example, for 1999, c. 16% of all microbial tests in the industry were for specific pathogens, c. 16% were for yeast and mold, c. 31% were for coliform and *E. coli*, and c. 37% were for total viable organisms. The same statistical survey found that microbial testing in each of the food sectors was as follows: 36% for the processed food sector, 10% for fruits and vegetables, 22% for meat, and 32% for dairy. The US food industry performed c. 144.3 million microbiological tests in 1999. Unfortunately, heavy reliance is still placed upon conventional culturing techniques, so there are significant time gaps between sampling for microbial contamination and detection of microbial contamination, and these techniques are often labor-intensive and require expertise in interpreting results. Other investigators also point out the importance of pathogen detection in the food industry, that is, that the food industry accounts for c. 38% of total research in the field of pathogen detection. The other major areas of research interest for biosensors are water and environment quality control (16%) and clinical applications (18%). In terms of research articles describing biosensors applied to pathogen detection, a review article, 'Pathogen detection: A perspective of traditional methods and biosensors', summarizes a number of interesting points. Thus, of research articles concerning pathogen detection, techniques for detection of *Salmonellae* species are the most abundant (33%), followed by *E. coli* (27%), with *Listeria*

(14%) and *Campylobacter* (11%) species the other major pathogens. *Legionella* account for 7% of research articles discussing detection techniques with all other bacterial species accounting for 8%. This relative abundance of research articles published with regard to detection schemes clearly indicates the emphasis upon pathogen detection for food safety. This same review also discusses some relevant statistics regarding detection technologies for pathogens, gleaned from a review of the relevant literature over the past 20 years. The most popular methods by far relate to culture/colony counting with PCR following closely behind. ELISA assays are in third place in terms of abundance, with biosensors following in fourth place. In the biosensor category, the most used techniques are optical (35%), followed by electrochemical (32%), piezoelectric (16%), and all other categories (16%).

The tried and true methods of microbiology involve concentration of microbes from food samples. Plating, culture, growth in selective media, and colony counting are still the gold standard with regard to identification and quantification. Nevertheless, as pointed out above, these techniques are time- and labor-intensive and do not provide answers in a timely manner. Even PCR often requires a time investment of several hours (at minimum) before analysis is complete, and also relies on technical expertise. There is clearly a need for rapid, low cost techniques that provide automated or semi-automated pathogen analysis. Even better would be systems which integrate all aspects of the analysis from sampling to final quantitative result. Biosensors seem well-suited to fill at least some of this niche in the food safety testing market. Yet, a main problem facing all such attempts to move pathogen testing from classical microbiological procedures to biosensor-based analysis is the issue of sensitivity. Recent literature indicates that the infectious dose of *Salmonella* or *E. coli* O157:H7 is ten organisms, while the existing coliform standard for *E. coli* in water is 4 cells/100 ml. Culture methods can and do attain this sensitivity. From a review of recent biosensor literature the present authors carried out, this level of sensitivity is not achievable by most of the biosensor research devices currently proposed. It seems clear that biosensors will only see their full potential realized with regard to pathogen detection for food safety, when specificity and sensitivity can compare to established methods and such biosensors can also be cost-competitive (or cost-saving) with current techniques. It should also be pointed out that testing for genetically modified organisms (GMOs) will probably become a more frequent analysis with regard to food and some authorities expect this area to see the fastest growth of any testing market in the food industry. Biosensor research for GMO detection seems to be mainly focused on DNA-based detection technologies at present.

Biodefense Biosensing Applications

Events of recent years have indicated the need for sensors of pathogens/toxins which could be used by military enemies or for terrorist purposes. Much research effort is currently focused on analytical strategies to detect these agents. A major difficulty with biological attacks is actually determining whether the attack has occurred, in a timely manner, to enable early response, and minimize casualties. The ideal sensor for biological agents which could be used for attack (hereafter called biowarfare agents (BWAs)) would provide highly sensitive and selective identification of threat organisms in virtually real time. Also, since the potential release of BWAs could be on the battlefield or in urban settings, the surrounding environment/atmospheric milieu may be highly complex (smokes, dust, and particulate matter), and the analytical technique must be able to detect organisms of interest without interference from background material. To date, these requirements have provided a daunting analytical challenge.

Attempts to meet this challenge have employed molecular techniques that can identify chemical markers of BWAs. In general, detection of BWAs can follow one of two paths. In one, positive identification of a BWA must be obtained in a few hours, the so-called detect-to-treat option. Such detection would give medical personnel the means to successfully treat individuals that have been exposed to BWAs. The time frame of several hours makes the analytical task easier than is the case with the other detection scenario. In this latter case, a detect-to-warn sensor must be able to provide a warning within a few minutes that a BWA release has occurred. If such sensors could be developed, then perhaps therapeutic treatment of all members of an exposed population might be an option. The variety of BWA that potentially could be used, that is, bacteria (vegetative or spores, Gram-negative or Gram-positive), viruses, and toxins, adds difficulty to the sensing task. Specificity and sensitivity are both critical for useful BWA sensors. False positives are unacceptable due to the consequences attendant upon an assumed BWA incident. False negatives are also unacceptable for obvious reasons. It is true that nucleic acid-based biosensing technologies have been demonstrated to have the sensitivity to detect one organism or one spore. Also, in general, nucleic acid-based sensing systems are more sensitive than antibody-based detection systems. Such analyses, however, depend on amplification of the target nucleic acid, a process that takes time (although intensive efforts have been and are being made to shorten this step). Further, nucleic acids from nonrelevant sources may interfere in PCR amplifications, and nucleic acid-based detection will not work for toxins. Detection of BWA with extreme sensitivity is important since some of the organisms manifest infectivity at extremely low levels. Nucleic acid-based detection also offers the best chance for detection of novel, engineered organisms or so-called stealth organisms, where virulence genes are inserted into an otherwise innocuous microbe. In these cases, the nucleic acid sequence of the virulence elements still provides a diagnostic signature. Integration of all steps (lysing cells/spores to prepare nucleic acids, amplification of target sequences, and detection of the same) required for nucleic acid sensing is crucial for a true biosensor, and so far, reducing the entire assay time to a few minutes has been unreachable. Thus, there has been interest in nucleic acid-based techniques that provide gene-based specificity, but do not require amplification steps to attain detection sensitivity to the required levels. Such exquisitely sensitive detection almost precludes techniques like SPR and recommends procedures like fluorescence detection.

This difficulty has led others to suggest that detectors based on surface features (e.g., immunogenic molecular species) of the threat organisms may be a more tractable route for development of detect-to-protect devices. Such devices must have a rapid response, must not give false positives, must have high sensitivity and the ability to detect the target in aerosol samples, when the natural environment for most detecting biomolecules is aqueous. The major factors for successful immunosensing of BWA are the

efficiency of the antigen–antibody complex formation and the ability to sensitively detect these complexes. Nonspecific binding can be a problem for such techniques, particularly as sensitivity is pushed. There is also an urgent need for multiplexed detection in BWA sensors, since the list of potential BWAs, while not overly long, still numbers more than a handful.

New Biosensing Directions

In this section, we wish to highlight several areas of biosensor research and development which, in our opinion, either already have demonstrated, or have the potential to demonstrate novel and powerful sensing capabilities. We will briefly discuss each of the technologies we wish to highlight in the following text. Some areas which we see as having unusual potential for application to a variety of sensing needs are: (1) virus-based biosensors; (2) genetically encoded biosensors based on fluorescent proteins; and (3) nanomaterials, and their applications as components of biosensors.

Virus-Based Biosensors

Viruses continue to intrigue researchers because of their varied structures and range of capabilities, all contained in packages of such small size. As structural entities, viruses can be thought of as highly structured nanosystems with a well-defined 3-dimensional structure which can occur in a wide variety of shapes and sizes. Of particular importance for sensing applications, viruses are characterized by multiple identical repeating units of coat proteins (thus providing numerous identical sites for scaffolding of various ligands and tags), water solubility, stability in aqueous buffers and perhaps most importantly, particles of a single type of virus are essentially identical and thus mono-disperse in size and shape. Because of the repeating nature of the coat proteins, attachment of modifying molecules at precisely defined positions is possible. Thus, fluorescent dyes can be bound at defined positions to make a ‘super-bright’ viral particle in which the spacing between dye molecules is such as to mostly eliminate fluorescence quenching, while multivalent display of ligands on the viral surface can improve binding affinity for cellular targets. By using site-directed mutagenesis it is also possible to express new reactive residues on the viral coat proteins. It is also possible to modify the viral coat protein to display not only fluorescent tags, but also targeting ligands, such as antibodies. The use of phage display to genetically engineer the capsid proteins of filamentous bacteriophages to produce recognition peptides of almost unlimited specificity for any target analyte has already been mentioned in this article and will not be discussed further here. Bacteriophages (afterward shortened to phage) are not the only viruses of interest as sensing moieties, however, as a variety of plant viruses such as cowpea mosaic virus, tobacco mosaic virus, and turnip yellow mosaic virus have also been employed. It is also possible to use the interior compartment of viruses, once the nucleic acid is removed to entrap entities such as nanoparticles, polymers, enzymes, fluorophore tags, etc.

Only in recent times has the potential usefulness of viruses as sensing entities been exploited. Not surprisingly, phage-based sensors have been applied in a variety of ways: (1) as target-recognizing probes (think antibody substitute); (2) peptides isolated from phage display techniques and used directly as probes; (3) lytic phages used directly as sensors by means of lysing their target bacteria and detection of components of lysed contents; and (4) phages conjugated to other nanomaterials to form a composite sensor. Phages have been immobilized on the surface of a QCM and used for the detection of pathogenic bacteria. Phages displaying specific peptides on their major coat protein have also proven to be effective replacements for antibodies in ELISA-type assays. In a similar manner, phages have also been used as sensing elements in immunofluorescence assays, in SPR detection and in electrochemical sensors. As already mentioned, removing the interior contents of the virus and using the interior cavity for encapsulation of various reagents is a novel modification which is just now being explored. Such constructs are referred to as virus-like particles (VLP). A natural property of intact virus is binding between viral coat proteins and specific receptors on cell surfaces. Thus, VLP can retain this binding specificity, while carrying labeling reagents on the interior surface. For example, canine parvovirus, which has a natural affinity for transferrin receptors, could be modified into VLP containing a fluorescent label. These labeled VLP became a biosensor for certain tumor cells which express transferrin on their surface.

Genetically Encoded Biosensors using Engineered Fluorescent Proteins

This remarkable group of naturally fluorescent proteins, occurring in the biological realm in certain sea creatures, have proved to be powerful tools for elucidating information regarding complex biological interactions. Perhaps some measure of their significance to biological research can be gleaned from the fact that the 2008 Nobel Prize in Chemistry was awarded to three investigators (Shimomura, Chalfie and Tsien) who played pivotal roles in isolation, study and application of these proteins to biological systems. Isolation of the first green fluorescent protein (GFP) from the *Aequorea victoria* jellyfish was followed by eventual sequencing of the gene coding for the fluorescent protein, and the discovery that the fluorescent protein (FP) could be expressed in virtually any cell, not just in species of origin. Clever site-directed mutagenesis has produced variants of GFP which have enhanced fluorescent properties relative to the native protein, and which have different excitation/emission maxima, e.g., CFP (cyan) and YFP (yellow) being among the most useful. Further studies of various Anthozoa species (reef corals) have permitted the color palette of FP's to be greatly extended into the orange and red regions of the visible spectrum. These studies have spawned a wide variety of modified fluorescent proteins with enhanced fluorescence emissions and with fluorescence properties spanning essentially the whole visible spectrum. Recently, expansion of the FP spectrum into the near IR has also been reported, using a bacteriophytochrome from a microorganism.

To understand the applications of these FP's to biological science, a few words need to be said about the FP structure. The tripeptide responsible for the fluorescence of FP's is in a central alpha helix which is enclosed in an 11-stranded beta barrel structure. The size of the FP varies between 20–30 kDa. Mutations within the chromophore site, as already alluded to, can result in changes in fluorescence properties. Once the gene for the GFP was identified and sequenced, it was found possible to place it under control of promoters and express the protein in, for instance, animal cells. This application, however, was by no means the most significant use of FP's. It was found possible to fuse the FP gene to other protein genes, whilst still retaining the fluorescent properties of the FP. This immediately led to tremendously diverse applications, as the FP could be fused to protein scaffolds which could act as molecular recognition elements or subcellular localization signals. Thus the FP's can become biosensors, reporting on molecular interactions in addition to protein localization with heretofore unachievable spatial and temporal resolution.

A powerful advantage of these fluorescent proteins (FP's), as compared to sensor molecules such as Quantum dots or fluorescent probes, which by definition are exogenous to the cell, and must be introduced by various techniques, is that FP's are introduced into cells as a genetic construct, and therefore are manufactured directly by the cellular machinery. Thus these genetically encoded fluorescent probes, by definition, are noninvasive. A further advantage of these FP's is that they can be directed to certain subcellular compartments by incorporation of signal sequences which control subcellular localization, while exogenous fluorophores may be constrained to only certain subcellular compartments. Fusion constructs of FP genes and other protein genes are easy to construct by standard molecular biology techniques. The potential to resolve molecular events on the time scale of 100's of milliseconds exists using these FP probes. Further, the use of FP's coupled with FRET-based techniques (see below) allows one to capture the intricacies of spatial interactions on a distance scale which has been difficult or impossible to achieve by other techniques. Also, using FP's allows one to gain information about biorecognition processes in the natural habitat of the proteins of interest, thus providing information about processes occurring within the complex environment of living cells, as opposed to the test tube.

Applications of FP's span an enormous spectrum of investigations. Here we can only provide a generalized overview with emphasis on common thematic elements. Fusion chimeras of FP's and a molecular recognition element (MRE) can either involve an endogenous or exogenous MRE, with the changes in FP properties being the sensor endpoint. On the other hand, FRET-based sensors, by analogy, may involve either intramolecular or intermolecular FRET interactions occurring as MRE's on the same protein chain or separate protein chains interact, with alterations in FRET properties as the endpoint. Also, the FP chromophore may be fragmented into two parts, with the biorecognition event reconstituting the intact chromophore. Some further explanation of these possibilities with examples will now be provided.

Perhaps the simplest application of an FP/single polypeptide chain fusion is in studying colocalization of separate proteins to subcellular compartments. Here, the use of two FP's with quite different fluorescent properties, each fused to one of a pair of proteins under study, permits the imaging of the chimeras in various subcellular compartments and evidence either for or against colocalization. In terms of FP's with endogenous MRE's, a variety of biosensors have been developed where changes in pH or ion concentration, etc. can produce changes in fluorescence properties of the FP. In these cases, the FP itself serves as the sensor, i.e., the analyte directly influences the FP's fluorescence properties. Fusion to other polypeptides may or may not be necessary for its intended use. Due to the chromophore's environment within the protein, GFP demonstrates alterations in fluorescence properties as pH changes. Thus, with FP fused to organelle-specific targeting peptides, a subcellular pH sensor has been constructed, providing information about pH of various cellular compartments. FP constructs have been made to serve as halide sensors, in which fluorescent properties of the FP change upon halide interaction, although here the additional requirement of engineering an ion channel into the chromophore part of the FP structure is needed to make the sensor effective. Also, interestingly, a redox sensor has been constructed in which site-specific mutagenesis has produced two cysteines in close enough apposition to the chromophore element of the GFP so as to alter the fluorescent properties depending on the redox state of the cysteines. If the cysteines are oxidized to a disulfide pair, there is a ratiometric change in the excitation spectrum of the GFP which can be monitored. This particular GFP has been fused to a human glutaredoxin, which increases the specificity for the reduced glutathione/oxidized glutathione pair and abolishes the dependence on endogenous glutaredoxin. Using this sensing fusion FP, it has been possible to examine oxidation states in mitochondria in real time and in vivo.

In the case of exogenous MRE's fused to FP's in which the total construct is still one polypeptide chain, an ingenious technique is used to generate the sensing structure (these constructs are sometimes referred to as circularly permuted GFP's). Here, the original amino and carboxyl terminal amino acids of the FP are connected with a flexible peptide linker, while in some other location within the FP structure, a peptide bond is broken and an exogenous MRE is inserted at this point. The FP structure is not so perturbed as to lose all fluorescence properties, but when analyte binds to the MRE, inducing a conformational change, this change is relayed to the chromophore, resulting in altered fluorescence properties. Thus, for example, a Ca sensor was devised where calmodulin was inserted in the fusion construct in such a location, that upon Ca binding, a large change in fluorescence emission was seen. A sensor giving information about relative ATP:ADP concentrations was developed by inserting an adenylate-binding protein into the YFP structure. Shifts in excitation spectra resulted when different ratios of the two ligands bound to the adenylate-binding protein. Other sensors in this class include hydrogen peroxide and Zn sensors.

We now discuss the FRET-based biosensors which employ various FP pairs. These sensors provide potential for incredible spatial resolution of molecular interactions. This is by virtue of the fact that FRET is an energy transfer process which is critically dependent upon both distance and orientation between donor and acceptor groups. In fact, effective distances where FRET interaction occurs are usually considered to be 10 nm or less. This is well below the standard fluorescence imaging resolution of 100's of nm. Thus FRET provides an insight into molecular interactions which is hardly to be obtained by other means. In intramolecular FRET configurations of FP sensors, two different FP's (most often CFP and YFP) are fused in tandem to a polypeptide sequence which is an

MRE. Upon binding of the analyte to the MRE, there is a change of structure of the peptide chain, which results in an alteration of the distance between the donor and acceptor fluorophores of the FRET pair. This in turn causes a change in the efficiency of FRET, which is the signal change that is detected. For example, if two FP's are within FRET interaction distance and separated by a peptide sequence which is sensitive to a particular proteolytic enzyme, presence of that enzyme will result in cleavage at the peptide site, thus separating the two FP's and abolishing FRET interaction, a result easily distinguished by loss of acceptor emission. Intramolecular FRET is also a powerful tool for studying the action of kinases, enzymes which phosphorylate various sites in proteins and have critical roles in regulatory cascades. In this sensor format, a peptide substrate for the kinase of interest and the binding domain for phosphorylated substrate are both fused to two FP's which form a FRET pair. When the kinase encounters this substrate, and phosphorylation occurs, the binding domain binds to the substrate, there is a rather large change in conformation, and the FRET interaction between the FP's is altered, which is detected by spectroscopy. This same general paradigm has been applied to other types of sensors. Bacterial periplasmic binding proteins, for instance, can have binding pockets specific for certain sugars. When the specific sugar binds, the more open configuration of the protein becomes more condensed, and FP's on either side of the binding pocket can come into FRET apposition. Calcium sensors called chameleons have been developed in which calmodulin, and M13 peptide are fused to CFP and YFP. In the absence of Ca^{++} , the fusion protein assumes a dumbbell shape and distances between the FP's are too great for FRET, but upon Ca^{++} binding, configuration changes to a compact shape and FRET is now detectable.

Analogous to the above FRET analysis system, it is possible to use intermolecular FRET-based assays, in which the two FP's are fused to two distinct polypeptide chains. Here again, if protein/protein interaction occurs upon presence of the analyte, FRET interaction can occur. These assays become somewhat more complicated because two separate fusion constructs must be co-transfected. A biosensor for cAMP has been constructed using this principle, in which two FP's of a FRET pair were fused respectively to the regulatory RII and catalytic subunits of protein kinase A, the main effector of cAMP. Protein kinase A consists of a holotetramer composed of two regulatory and two catalytic subunits. Activation of protein kinase A by cAMP causes dissociation of the catalytic from the regulatory subunits. In the FP-labeled intact protein kinase A, FRET interaction occurs. Upon binding of cAMP, dissociation of the two subunits is induced, resulting in loss of FRET energy exchange. The same type of intermolecular FRET can be used to examine other protein-protein interactions.

Yet another type of sensor strategy is available for FP-based sensors. This is referred to as bimolecular fluorescence complementation. The principle here is that a biorecognition event (analyte binding) brings together two fragments of a split FP into close enough apposition so as to effectively constitute an active chromophore (i.e., by refolding into the beta barrel structure). Another way to conceptualize this is to think of a MRE fused to one FP fragment and an analyte protein fused to another FP fragment. Upon interaction of analyte portion with MRE, a 'reconstituted' active chromophore is generated. This type of sensing strategy has been used to study the interaction between three protein subunits that constitute the influenza A polymerase complex, and to examine oligomerization between adenosine $\text{A}_{2\text{A}}$ and dopamine D_2 receptors.

It is not possible in this brief review to give more than a taste of what can be done with these very versatile FP reporters. The subject should not be left, however, without mentioning some potential difficulties associated with use of FP fusion constructs, as well as very recent developments. Unfortunately, because the FP's themselves are quite large proteins, the size of fusion constructs can cause deterioration of the fused construct. Also, the cell may mislocate the fusion protein, again probably because of the hybrid structure of the construct. The FRET-based applications, while potentially very powerful, are very dependent not only on distance but *orientation* of the adjoining fluorophores, and orientation may be critically changed in complex protein constructs. Also, FRET, while seemingly conceptually straightforward, is, in practice, somewhat more complex, and ratios of fluorescence changes between donor and acceptor molecules must commonly be examined, when attempting to assess conformational changes as monitored by FRET.

In spite of these caveats, the use of genetically encoded fluorescent biosensors bids fair to provide us with ever greater insights. One can envision a complete repertoire of these biosensors, each with specific properties that will allow interrogation of the status of the event under examination. Furthermore, other more advanced spectroscopic techniques like fluorescence lifetime imaging and fluorescence recovery after photobleaching, will permit more detailed analysis of these various FP fusion hybrids as they interact in sensor configurations. Finally, recent developments herald the applications of so-called photoactivatable or photoswitchable FP, which have been termed optical highlighters, in which illumination of the FP at certain wavelengths can produce photochemical reactions that change the properties of the chromophore. These optical highlighters have enabled imaging of fast protein dynamics and sub-diffraction limit imaging.

Nanomaterials and Applications to Biosensors

Introduction

The recent development of nanomaterials science has produced an incredibly rich array of novel materials which are likely to find multiple applications, among them being as components of biosensors. Various inorganic nanomaterials have been produced and characterized, including nanoparticles (metals, for example, gold, silver, iron), nanocrystals of semi-conductors (e.g., Quantum Dots [QD's]), nanorods, nanowires, and various carbon nanostructures (both single walled and multi-walled carbon nanotubes, nanofibers, etc). This list is not by any means all-inclusive, as more complex geometric shapes and various hybrid structures are being continuously developed. The field is so vast that it is not possible to cover every recent development in a short review.

Rather, in this article, we hope to focus on general principles which are being utilized in numerous applications of these nanomaterials to biosensing, and to provide a few examples illustrating such applications.

What then are the potential advantages which nanomaterials bring to biosensing applications? Due to their extremely small size, these materials have unique physical properties which recommend them as scaffolds for biosensing. Included among these properties must be items such as electrical conductivity, unique optical properties, unique structural characteristics (i.e., very high surface area-to-volume ratio), and certain biological properties predicated upon their nano-size. Indeed, the nanometer-size scale of these materials allows relatively facile entry into cells, providing potential for intracellular sensing, although the innocuousness of these materials within the cell is still somewhat of an open question. The large surface area of these materials allows derivitization with many biologically active ligands, and the resultant high density of such bioreceptors may increase affinity toward target molecules by a multivalent binding effect, while also shortening the response time for sensing. In the ideal case, nanomaterial-based sensors would selectively bind to the intended target, without interfering with the underlying biological process, and produce a strongly amplified signal which could be detected with commercially available detection technology. An inherent advantage of nano-sized materials as sensors, in general, is that the devices based upon such materials probe a much smaller volume or surface area than macro- or even micro-sensors. Thus, the total amount of analyte required to produce a measurable transduction signal is significantly lower, and so the limit of detection is (sometimes) greatly lowered.

How are nanomaterials utilized for biosensing applications? This is a complex question to answer, as innovative paradigm shifts are being constantly developed, but some general principles can be elucidated. First, nanomaterials may be used as scaffolds/platforms upon which to immobilize various biomolecules which are the actual biosensing element. Thus biorecognition molecules such as antibodies, aptamers, nucleic acids, carbohydrates, proteins, lipids, and subunits of the preceding, may all be immobilized (absorbed, covalently linked, etc) onto nanomaterials. Second, nanomaterials may bring unique capabilities to transducer output (i.e., signal which is detected) compared to conventional transducer mechanisms. For example, carbon nanotubes (CNT) have unique electrical conducting activities, making them highly useful for electrical sensing applications such as field effect transistors, electrochemical sensors, etc. Third, homogeneous or solution phase sensing using nanoparticles which have been functionalized to both capture analyte and serve as a detection platform are also being developed. As opposed to detection on surfaces, solution sensing has the potential advantage of more rapid and efficient kinetics in terms of analyte binding. For such applications, quantum dots have received much attention recently. Also, gold nanoparticles show unique optical changes depending upon degree of aggregation, thus forming the basis for colorimetric sensing applications. Gold nanoparticles provide ready-made surfaces for SPR sensing, while gold nanorods can serve as interdigitating electrodes for electrical sensing applications. Nanoparticles can also serve as intermediaries to increase sensitivity of detection in such sensing devices as QCM's and micro-cantilevers. Here the nanoparticles, appropriately derivitized so as to bind to a specific analyte, add further mass to the microbalance or cantilever, thus hopefully increasing the sensitivity without sacrificing selectivity.

Third, nanomaterials, by virtue of their size, are potentially very attractive intracellular biosensing probes. Entry into the cell can be a problem, but not necessarily always is. For instance, cells may endocytose nanomaterials, particularly if they are decorated with biomolecules or bio-like-molecules. Once inside, the nanomaterials can provide unique advantages for sensing applications, for example, the outstanding fluorescence intensity of the quantum dots. Further, biomaterials (nucleic acids for example) show increased stability and protection from intracellular degradation when coupled to nanomaterials. Some studies have indicated that the nanomaterials have little or no toxicity upon intracellular introduction, but this issue still needs further investigation. Coating the nanoparticle with an inert or biocompatible matrix has been investigated as an approach to mitigate any toxicity issues. Finally, nanomaterials may serve as molecular barcodes, that is, as identification elements which can serve to uniquely tag specific analytes. As such, they can provide multiplexing capabilities for bioassays. We now provide some examples, by no means comprehensive, of how nanomaterials have been utilized in biosensing applications.

Nanomaterials as Biosensors: Examples of Nanofiber-Based Systems as Integrated Biosensor Devices

An example of a nanomaterial biosensor that realizes all three of these criteria, i.e., molecular scaffolding, integrated transduction mechanisms, and intracellular deployment, is the vertically-aligned carbon nanofiber or VACNF. The VACNF is a unique subclass of carbon-based nanomaterials whereby plasma enhanced chemical vapor deposition is used to synthesize vertically-aligned high aspect ratio carbon spikes on a variety of growth substrates. VACNFs are compatible with most microfabrication processes including chemical and physical deposition techniques, chemical and physical etch processes, lithographic patterning, chemical/mechanical polish, etc., and thereby can be incorporated into complex multifunctional devices featuring VACNFs as nanoscopic components of mesoscale systems. The physical, chemical, and morphological characteristics of VACNFs provides a nanostructured element well suited for biosensor applications.

VACNFs are formed of stacked cones of graphitic carbon 'cups' that can either be directly functionalized to provide scaffolding for biomolecular reagents, or modified using various chemical or microfabrication techniques to enable indirect functionalization strategies. McKnight et al. (2006) demonstrated a variety of direct functionalization strategies that could be spatially defined using photoresist masking laterally across the surface of VACNF-array populated samples, as well as vertically along the height of these vertically-aligned elements. EDAC chemistry (1-ethyl-3-(3-diaminopropyl)carbodiimide) was used to spatially modify exposed VACNFs and VACNF-tips emergent above a photoresist layer with a variety of biomolecular species including DNA, streptavidin, and biotin. The latter could be used to capture streptavidin conjugated quantum dots, FITC-streptavidin, and peroxidase avidin. VACNFs have also been surface modified for subsequent functionalization, acting as scaffolds for example for deposition of

electron-beam evaporated gold films, whereby only the extreme tips of nanofibers emergent above a photoresist layer were gold modified, and later used for thiol affinity capture of active enzymes, nucleic acid probes, and full length copies of linearized or circular plasmid DNAs.

The microfabrication compatibility of VACNFs have also made them attractive candidates as fully-integrated transduction elements in biosensor devices. Using lithographic techniques, individual VACNF elements, or arrays of multiple high aspect ratio VACNFs, can be integrated into electrically addressable electrode systems, whereby the high aspect ratio carbon spike or even just its extreme tip can be deployed as the active element of a much larger mesoscale device. [Guillorn et al. \(2002\)](#) demonstrated the first integration of an electrically addressable array of individual VACNFs in a microfabricated device, verifying the electrochemical performance of individual spike tips using cyclic voltammetry of a redox active couple, ruthenium hexamine trichloride. Subsequent efforts have demonstrated site specific functionalization of individually addressed VACNF elements, such as via the electrodeposition of polypyrrole (pPy) and enzyme doped pPy-films; site specific transduction of molecular events occurring at nanofiber tips, including the exocytotic bursts of neurotransmitters from nearby cultured cells ([McKnight et al., 2006](#)); and electrophysiological interrogation and stimulus of organotypically cultured hippocampal slices ([Yu et al., 2007](#)).

Perhaps the most exciting aspect of VACNF-based devices is the ability to incorporate the high-aspect ratio carbon spike, and spike arrays, as intracellular elements that can be assimilated into the working microenvironment of individual or multiple cells. [McKnight et al. \(2003\)](#) demonstrated that when functionalized with covalently bound plasmid DNA, VACNF spike arrays could be introduced into the intracellular domains of many cells in parallel, and that cellular survival was maintained, even over long time periods (22 days) with the residence of individual spikes being retained in some cells. Subsequent applications of this technique have been used for a variety of gene and macromolecular delivery applications, including introduction and expression of covalently tethered DNA, releasable DNA cargoes using disulfide linkages cleaved via intracellular esterase activity, and protein localization and mislocalization studies via delivery and expression of fluorescent protein labelled gene products. Intriguing aspects of these demonstrations include the potential for achieving a genetic modification that is non-inheritable and whose extent in time can be directly and precisely controlled, and the potential of VACNF arrays as an intracellular interface for monitoring and controlling subcellular and molecular phenomena within viable cells for applications including biosensors, in vivo diagnostics, and in vivo logic devices.

Nanowires and Nanocrystals as Biosensors

The configuration of semiconductor nanowires (NW) as field effect transistors (FET) has opened new horizons in highly sensitive biosensing. In this arrangement, a single NW (for example, a silicon nanowire or a carbon nanotube) is placed between two patterned microscale contact pads, one of which is the source and one of which is the drain, in analogy to FET's. Binding of analytes to NW surface (either directly or more commonly via bioreceptor) produces a change in the electric field or potential at the NW surface, which in turn, results in a change in conductivity. Silicon NW's can have diameters as small as 2–3 nm. These small structures, on the same order of size as macromolecules, have a tremendous advantage over macro sensors because a smaller number of analyte molecules are able to produce a measurable change in NW electrical properties, due to the wire's nano-dimensional size. The binding of macromolecules to the NW surface can lead to depletion or accumulation of charge carriers over the bulk of the NW (thus changing the conductance), while with a planar FET, only the surface region of the transistor is affected. Commonly, as mentioned previously, the NW's are modified with biorecognition molecules which can bind the analyte of interest. In the case of silicon NW, the oxide layer that forms on the surface facilitates derivatization. When the NW FET is exposed to a solution of the analyte, binding takes place, and depending upon the net charge of the analyte in aqueous solution, either an increase or decrease in net negative NW surface charge takes place, with a corresponding increase or decrease in conductance, which is detected by measuring current flow between the electrical contacts. A potentially very important advantage of NW FET's is the fact that no labeling of the analyte or bioreceptor is needed for successful detection to take place. In principle, the concept of NW FET's is straightforward. One important consideration for successful functioning is to insure the use of aqueous solutions of low ionic strength, since high ionic strength buffers or biological solutions of high ionic strength interfere with the conductance. Several examples of biosensing applications of NW FET's follow. Reviews of this area have been published by [Wanekaya et al. \(2006\)](#) and [Patolsky et al. \(2006\)](#). Silicon is not the only material of use for nanowire FET's. Metal oxide nanowires have been used with success, such as ZnO, IrO₂ and In₂O₃. Further, conducting polymers have also been used, as have carbon nanotubes. Reproducible integration of these other materials with the electrodes is one of the present difficulties to their more widespread use.

Both proteins and nucleic acids, being generally charged in aqueous solutions, are readily detected by NW FET's. If peptide nucleic acid (PNA) sequences which are complementary to the DNA sequence of interest are attached to the NW, then hybridization of the polyanionic analyte DNA to the PNA can be detected. Importantly, PNA's need to be used as the bioreceptor, since they are uncharged. Direct electrical detection of single stranded DNA was possible down to at least 10 fM levels. Also, the NW FET could be used to detect single base-pair mutations. Thus, NW's modified with the complement of the wild-type sequence for one mutation site in the cystic fibrosis transmembrane receptor gene showed conductance changes in the FET upon hybridization to the wild-type gene sequence, while the sequence bearing the delta F 508 mutation would not hybridize with the complementary probe for the wild-type sequence and thus did not show a change in conductance. (The above work was reported in [Hahm and Lieber, 2004](#).) Proteins are equally amenable to detection. Thus, for example, detection of PSA (prostate-specific antigen) was carried out using NW elements which had antibody to PSA immobilized on their surfaces. Detection was possible even with PSA concentrations of ~2 fM.

Experiments with a different protein such as BSA or PSA pre-reacted with antibody to PSA showed no change in conductivity. It is also possible to construct NW arrays, to allow multiplexed detection of marker proteins, such as would potentially be of great value in defining cancer diagnosis. Patolsky et al. (2006) demonstrate this with an array of NW's which detected PSA, carcinoembryonic antigen and mucin-1 simultaneously, in real-time, at high sensitivity (femtomolar) and with essentially 100% selectivity. Interestingly, this same research group showed (by extensive and careful experiments) that a single virus particle could be detected on a NW FET in which the NW was modified with a monoclonal antibody against the virus. It appears that the future of NW-based FET's is bright considering their advantages, including direct, real-time, label-free electrical detection, coupled with great sensitivity and selectivity, along with the potential for development of integrated arrays (Patolsky et al., 2006).

Carbon nanotubes (CNT) can also be used as NW elements in FET's. Advantages over semi-conductor (i.e., silicon) NW include the fact that single-walled nanotubes have higher electron mobilities and diameters in the sub-nm range, making it possible to detect lower charge densities. On the other hand, the synthesis of carbon nanotubes is more difficult to precisely control as compared to synthesis of nanowires. Wang (2005) provides a review of this area. A particular advantage of CNT for electrochemical sensing is that it has been found that CNT can promote electron transfer reactions, particularly for redox enzymes, and can enhance the electrochemical reactivity of a number of biomolecules. For example, multiwall CNT carbon nanofiber arrays vertically aligned on an underlying electrode, act as molecular wires, which allow electrical communication between the electrode and redox enzymes immobilized on the CNT's. A variety of electrochemical techniques have been employed to detect glucose using CNT's as part of the electrode. Beside enzymes such as glucose oxidase, CNT's have also been used as facilitators for dehydrogenase reactions, as well as peroxidase and catalase reactions. CNT have also been utilized for electrochemical detection of DNA, that is, hybridizations to capture DNA molecules immobilized on electrode surfaces. Here again, vertically aligned CNT arrays have been found to be of great utility and can produce extremely sensitive analytic results.

The above discussion does not exhaust the types of nanomaterials being employed for biosensor use with electrical detection. For example, ingenious detection schemes for nucleic acids have been developed wherein gold microelectrodes were fabricated on silicon wafers, capture DNA strands were immobilized in the electrode gaps, and target DNA was captured within the electrode gaps. Then gold nanoparticles with an oligonucleotide complementary to the unhybridized end of the target DNA were added, hybridization took place, and gold nanoparticles were now immobilized between the electrodes. Subsequent coating with a silver layer increased electrical conductivity and sensitivity of the assay and lower limits of detection in the fM region were attained.

Kar and Shankar (2013) review the application of aligned one-dimensional arrays of nanotubes and nanowires constructed of various semiconductors. They provide a table comparing detection sensitivity for some common bio-analytes using both these types of structures (nanotubes and nanowires) and other transducers. For each analyte listed, the semiconductor nano-arrays showed better sensitivity of detection compared to other devices. Sensing techniques used included fluorescence, electrochemical, and FET. The increased sensitivity was attributed to greater efficiency of binding analyte/biorecognition element to the nanoroughened surface, along with increased sensitivity of transduction. The authors also provide a discussion of how these nano-arrays can be implemented for fluorescence, electrochemical, FET, and nanomechanical biosensing.

Quantum Dots – Nanoparticle Fluorescence

The development of semiconductor nanocrystals, called quantum dots (QD's), has had great impact upon the applications of fluorescence sensing for biosensors. The inherent weaknesses of organic molecule fluorophores can be largely overcome by these fluorescent nanoparticles. Quantum dots (typically CdSe, CdTe, CdS) have broad excitation spectra and also feature very narrow emission bandwidths, which can be tuned to various wavelengths depending on the size of the nanoparticle. A further advantage is good chemical stability. The name quantum dot is somewhat of a misnomer, as the structures are actually light-emitting semiconductor nanocrystals. The usual size of QD's are 2–10 nm. As the QD size increases, the emitted luminescence shifts to longer wavelengths. Among the advantages of quantum dots are size-tuned fluorescence emission, photostability (minimal photobleaching), high quantum yield, and the narrow, symmetrical emission profiles, thus facilitating multiple analyte detection in a given sample. The narrow emission profiles of QD's also facilitate their use in multiplexed assays and in FRET-based sensors. The very broad excitation spectral profiles of QD's allows excitation at a wavelength far removed (>100 nm) from emission maxima, so that multiple QD's with different fluorescent emissions can be excited with just one excitation wavelength.

The most common QD composition is CdSe, which forms the core, and has a thin shell of some other composition, frequently ZnS. The ZnS outer shell can facilitate conjugation of various molecules to the QD surface. Another strategy to link molecules to QD surfaces is to use a polyhistidine (usually 6 histidine residues) which coordinates to the Zn ions in the shell. Because of continuing concerns about the cellular toxicity of Cd, however, other semiconductor elements are beginning to be investigated for QD usage. Thus, InP/ZnS (core/shell) have been found to induce less oxidative stress genes in cells in culture than the usual Cd Se/ZnS QD's.

Modification of the surfaces of quantum dots is usually necessary to produce sites for biomolecules to bind, as quantum dots, in general, are hydrophobic after synthesis. Modification of the QD surface with biorecognition elements can be problematic both as regards orientation of the biorecognition element for most efficient target binding, as well as density of decoration on the QD surface. Peptide modification of QD surfaces has attractive features, since peptides can, in many instances retain the key biological activity desired for biosensing purposes, as well as retaining a separation distance between donor and acceptor molecules which can be compatible with FRET or BRET, a constraint which can be a problem with full-sized proteins. Nagy et al. (2014) provide a review of various biosensing applications of QD's conjugated with peptides. One of the commonest uses is as protease sensors, where the QD is conjugated to a peptidyl sequence which is a target sequence for a specific protease, and the distal end of the peptide sequence

has an acceptor fluorophore. If the peptide sequence is intact, the fluorescence of the QD is quenched via FRET, but when protease action cleaves the peptide at the target site, the QD recovers its fluorescence emission due to the acceptor being now separated from the QD. The same principle operates if, instead of an acceptor fluorophore, a Gold Nanoparticle (GNP) is attached to the end of the peptide, causing quenching via FRET or an organic quencher is used. Examples of proteases detected by this technique include caspases, serine proteases, metalloproteinases, and collagenase. It has been noted that GNP/QD FRET-based systems seem to, at least in some systems, produce better sensitivities of detection compared to QD/organic dye pairs, perhaps due to nanosurface energy transfer. Multiplexed assays of several proteases have been demonstrated using QD's with different emissions. Also, QD's can serve as the acceptor molecule rather than the donor in a FRET pair, and so donors like *Renilla* luciferase and mCherry protein have been used as donors in protease-type assays.

Besides proteases, protein kinase activities have been adapted to QD-based biosensing schemes. In these type assays, a similar FRET scheme is used as described above for proteases, but one of the FRET pair is an anti-phosphotyrosine (or anti-phosphoserine or anti-phosphothreonine) antibody coupled to a fluorophore, while the other member of the pair is a QD conjugated to a peptidyl substrate of the kinase being assayed. If the kinase phosphorylated the target peptide, the anti-phospho-antibody bound to the phosphorylation site, and FRET occurred, thus reducing the emission fluorescence of the QD. Other more complex assays have also been developed using QD's in which, for example, FRET 'relays' are produced where energy is transferred in turn from QD to one acceptor fluorophore and subsequently to another acceptor fluorophore.

Delivery of QD's intracellularly is of great interest, as the outstanding optical properties of QD's recommend them for a variety of intracellular sensing applications. Thus, investigations have focused on modifying QD's with cell-penetrating peptides, to facilitate cellular uptake. Uptake into the endosomal pathway seems to be a common theme, so that although the QD's indeed become intracellularly localized, they do not, in general, leave the endolysosomal pathway so that targeting to other intracellular locations is still not readily realized. Some examples of intracellular sensing using QD's include intracellular pH measurements and intracellular protease activity,

A very interesting application of QD's is their use as a type of optical barcode, which can be used as a sort of microchemical lab. To implement this concept, QD's of different sizes (and thus different colors in regard to emitted light) are incorporated in precisely defined ratios into a polymer microbead. The polymeric microbead is easily derivitized with biorecognition molecules, such as antibodies or nucleic acids, while each different bead species has a unique ratio of QD's. Thus, for each bead type having a unique biorecognition element, that same bead type will have a unique color/intensity code for facile target identification. The fact that all the QD's can be excited with one excitation wavelength makes this assay possible. The investigators who developed this assay found that the QD's embedded in the polymeric sphere were separated enough spatially that FRET did not occur. Han et al. (2001) estimate that at least 10,000 recognizable QD-based codes could be developed. The authors provide some bioassay results using this scheme.

The use of QD in combination with electrodes for sensing of analytes is a topic of recent interest. Quantum dots may be immobilized on electrode surfaces, and then illuminated with light, which thus generates charge carriers and produces a current. Analytes at the electrode surface which can act as electron donors or acceptors can modify this current. An important point to consider in such an analysis is that only at the point at which light is illuminating the electrode do the reactions occur. Thus, if different biochemical systems are immobilized at spatially different sites, there are possibilities for multiplexing, when different sites are illuminated sequentially. There is another possible analysis which can take place in a system where QD's and electrodes are coupled. Here, if the electrochemical reactions taking place at the electrode surface generate light (electrochemiluminescence), then this light can be used as an excitation source to induce QD luminescence. Lisdat et al. (2013) provide a review of this developing field.

Quantum dots are not the only nanomaterials with intrinsic fluorescence properties. Graphene oxide also has intrinsic and tunable fluorescence. Fluorescent grapheme-based materials are also being investigated as sensors. Long et al. (2013) provide a brief overview of this subject.

Other Nanoparticle-Based Biosensing Modalities

Optical nanoparticle sensors for intracellular detection of a variety of analytes, called felicitously PEBBLES, have been developed by Kopelman's group. Most of these sensors are not strictly biosensors by the definition of this article since they do not involve a biomolecule as a recognition element. Nevertheless, the principles involved lend themselves to broader applications. The nanomaterials involved in these sensors include quantum dots, polymeric nanoparticles (i.e., organic molecule polymer or silica-based) as well as metallic nanoparticles. The sensing element is generally an organic fluorophore, or in the case of quantum dots, the nanoparticle itself. A unique aspect of these sensor nanosystems is the inclusion of a reference fluorescent dye, along with the detecting fluorophore, which allows some measure of quantification. Another research group has developed a maltose biosensor using a maltose-binding protein as a receptor attached to a quantum dot. Maltose binding was detected by FRET changes, as a quencher molecule was displaced from the monosaccharide binding site.

Noble metal (Ag, Au) nanoparticles have also proven their utility for optics-based methods of detection. Gold nanoparticles (GNP) can be utilized as part of a FRET pair by virtue of their fluorescence quenching properties, and they can also participate in direct colorimetric assays, based upon color changes between the aggregated and non-aggregated states of GNP's of appropriate size. If gold nanoparticles are surface-modified with biorecognition elements such that presence of an analyte produces aggregation of the nanoparticles, the resulting color change can be a simple visual assay. Thus, by attaching complementary DNA oligomers to two

separate batches of nanoparticles, the hybridization event could be detected by a change in color of the solution. Interestingly, the melting point profile for the hybridized DNA oligomers attached to nanoparticles showed very sharp transitions, apparently due to the nanoparticle attachments. Thus, due to the sharp transitions in melting temperature, it was possible to adjust the sensitivity of this assay so that single base pair mismatches could be detected. To detect specific nucleic acid sequences (target sequences), an assay format was developed in which capture oligonucleotides complementary to part of the target sequence were immobilized to a solid substrate, and gold nanoparticles derivitized with oligonucleotides complementary to another portion of the target formed a sandwich, binding the target sequence between them. To increase sensitivity, a silver coating (so-called silver enhancement) was deposited upon the gold nanoparticles and the resulting surface was scanned in a flatbed scanner. This assay was found to be 100-fold more sensitive than an assay based upon conventional fluorophore techniques.

Gold nanoparticles have a variety of unique optical properties which recommend them for use in imaging and detection modalities. Investigators have developed striped metallic micron-length nanorod particles, termed nanobarcodes. Identification of the stripe pattern can be made by means of a microscope. Labeling these nanorods with various bioreceptors allows one to identify and quantify a number of biomolecule targets simultaneously. Mirkin's group have developed a technique, called nanoparticle-based bio-bar codes for ultrasensitive detection of proteins. Here two types of particles are used, one a magnetic particle which has a capture antibody attached to it, and another a gold nanoparticle with an antibody against another epitope of the antigen of interest attached to it. The antigen (protein) of interest is first captured by the magnetic particle, and subsequently the gold nanoparticle with second antibody also attaches to the antigen. The key to this assay is that the gold nanoparticle has also attached to it double-stranded (complementary) oligonucleotides, in which only one of the oligonucleotide strands is bound to the nanoparticle. Following separation by a magnetic field of the particle/particle complex from reactants and a dehybridization step, the released oligonucleotide becomes a 'bio-bar code' specific for the protein of interest and also the means by which that particular protein is detected. Since many oligonucleotides can be bound to a single nanoparticle, there is an enormous potential for amplification. The released oligonucleotide strand can be readily detected by a variety of techniques such as the silver enhancement assay discussed above or PCR. The sensitivity of this method for detection of a clinically relevant protein (PSA) was found to be approximately 6 orders of magnitude better than standard immunological (ELISA) techniques.

Applications of carbon nanotubes (CNT) and other carbon-based nanostructures to novel biosensing strategies continue to grow. A variety of properties of CNT's recommend them for sensing functions. Because of electron or energy transfer, single walled CNT's can serve as very effective quenchers for a variety of fluorophores. Thus, single walled CNT's have been substituted for organic molecules used as quenchers in molecular beacons, and have better quenching efficiency, low background and high signal-to-noise ratio. Other analytical arrangements in which single or double-stranded nucleic acids are linked to single walled CNT's have also been explored as platforms for optical sensing. Aptamer-based molecular beacons for protein sensing can also be linked to single walled CNT's. Single walled CNT's can also be functionalized with several different probes for multiplexed sensing. Single walled CNT's have also been used as transducing elements with a thrombin-specific aptamer, but in this case the CNT was employed as a field effect transistor. CNT's have also been used as electrochemical sensors with applications to a wide variety of analytes. The features of CNT's which make them most suitable for these applications include high electrical conductivity, rapid electrode kinetics, chemical stability and mechanical strength. Also, a biosensor based upon antibodies immobilized on CNT's for detection of specific antigens has been described in which electrochemical sensing is the detection endpoint.

Nanoparticles (NP's) of various descriptions continue to receive much attention as potential biosensing and imaging agents. This review is not, per se, directed to imaging agents and techniques. We highlight here two recent interesting applications of nanoparticles as examples of novel concepts, but emphasize there are many more techniques being developed. [Von Maltzahn et al. \(2011\)](#) developed a NP-based system which consisted of a so-called signaling module and a receiving module, with a natural amplifying step, which was the clot-forming (coagulation) cascade, ending with the formation of fibrin. The signaling module employed gold nanorods or an engineered human protein, designed to detect host vessels for tumor receptors. In the case of gold nanorods, there was passive targeting of tumor tissue, and the clotting mechanism could be activated at the tumor site by using near IR energy (laser light) which was transduced by the nanoparticles into heat. The localized heating disrupted the tumor vasculature, generating the clotting mechanism. Magnetic nanoworms were then derivitized with molecules which provided specific targeting to the elements of the fibrin clot previously generated. The presence of the nanoworms in the tumor tissue was detected by MRI. Using these strategies, it was found that there was up to a 40-fold enhancement in accumulation of the receiving module (magnetic nanoworms) using the coagulation cascade, as compared to accumulation in the absence of the cascade. This is a rather unique experimental system, using as it does, both natural (coagulation) and artificial (nanoparticles) components in which the artificial input (signaling module) and artificial output (i.e., magnetic nanoworms – 'receiving module') are joined to a natural biological pathway.

[Ghosh et al. \(2012\)](#) have described another unique system in which a bacteriophage (a natural biological entity) is used as a carrier of nanoparticles to deliver larger amounts of imaging agent, via specific targeting, to tumor targets. In this case, the key to success is the fact that the bacteriophage M13 can be genetically manipulated so that the coat proteins can be modified by genetic engineering for either foreign (that is, to the bacteriophage) peptide or protein display. In this case, one of the coat proteins (p3) is genetically modified so that it has a targeting ligand for a specific protein associated with various cancers. Another coat protein (p8) is genetically modified so that this protein has a net negative charge, and thus binds strongly magnetic iron NP's with net positive charge. Since the M13 bacteriophage is filamentous, the magnetic NP's, which are attached to the p8 coat in a longitudinal manner, align along the long axis of the phage with a length of ~800 nm, the approximate length of the phage. Approximately 26 MNP could be bound per phage. The p3 coat protein, on the other hand is located at one end of the phage, so that the tumor

recognition site and nanoparticle binding sites are spatially separated, potentially avoiding problems with either targeting molecule or imaging moiety functionality. Thus the engineered phage, carrying the MRI-imaging NP's can bind specifically to tumor sites by virtue of its targeting peptides on one end of the phage. This is a paradigm shift in terms of attempts to target NP's to tumor sites, since the usual approach is to derivatize NP's with multiple targeting ligands, for improved binding. Here, by combining the carrying capacity of the phage for imaging/detecting NP's it is possible to achieve multiple detector agents per every phage which binds to tumor-specific targets. Ghosh et al. (2012) further demonstrate the effectiveness of this system by demonstrating selective targeting in vivo, as well as improved targeting in vitro, compared to magnetic NP's which were derivatized with the same targeting peptide as was used for the ligand attached to coat protein p3 in the modified phage.

The list of applications in which nanomaterials are playing a crucial role could go on and on. This short summary will, perhaps, provide a flavor of the scope of the potential uses of nanomaterials. As more nanomaterials are developed, with more unique properties, the list of biosensor applications can only grow.

Concluding Remarks

The above discussion of biosensors shows that this is an emerging field that has not by any means reached its full potential. During preparation of this article, the authors reviewed many research papers with very ingenious ideas for biosensors. Unfortunately, the gap between biosensor prototypes that work in the laboratory and commercial biosensors which can see routine use in real-world environments is often still large. The many varied biorecognition elements, transducers, and detection strategies lead to a wealth of potential applications. The field of biosensor research/applications is still probably in the stage where it is not clear what biorecognition elements/transducers/detection schemes will be most productive, and indeed, this may well continue to evolve in different directions as techniques like MIP become more established. Also, the large number of potential applications may well demand a quite varied armamentarium of biosensor techniques. In general, robustness of the biorecognition element continues to be a concern for many applications. The use of transducers/detection mechanisms that involve sophisticated/expensive instrumentation also will preclude such devices from many routine applications. Simpler is not necessarily always better, but dipstick sensors for certain applications are attractive.

A few comments regarding two other areas which the authors of this article believe will have increasing importance in the field of biosensor applications in the future will close out this article. Array biosensors, biochips, labs-on-a-chip, that is, devices that permit multianalyte detection (multiplex analysis) and, ideally, that can integrate all processing steps into a microanalytical system, will certainly see increased interest in the future. Such integrated devices have a number of advantages, such as ability to assay large numbers of samples in minutes, savings of expensive reagents, and reduction in time for individual assay steps due to decreased assay volumes. Unfortunately, there are a number of obstacles still to be overcome with regard to these systems. Among these are such things as further development of microfluidics systems, sample preparation modules, sensitive detection modules, and robust assay methodologies. Another area receiving much recent interest is in the area of nanotechnology, more specifically the use of nanomaterials such as nanoparticles in biosensor development. Nanoparticles do not serve as biorecognition elements *per se*, but can be modified by attachment of appropriate molecular species (e.g., antibodies and DNA fragments) to become nanosized carriers of biorecognition elements which can also serve valuable transduction functions (i.e., magnetic properties and fluorescence). The unique properties of nanoparticles, that is, colloidal gold and quantum dots, also recommend them for novel sensing applications. A number of investigators have mentioned the potential use of nanoparticles, particularly quantum dots, as molecular bar codes. Metallic nanoshells and semiconductor quantum dots are highly promising markers for use in high throughput screening and barcoding, by virtue of spectral multiplexing. However, much work remains to be done before the full promise of these materials is applied to practical and useful biosensors.

Glossary

Adenopathy An enlargement involving lymph nodes.

Bioterrorism A deliberate use of biological agents (such as bacteria or viruses) or any other organisms as a weapon.
CDC Centers for Disease Control and Prevention.

Edema/oedema Synonym with swelling, it represents an abnormal accumulation of fluid in body cavities or beneath the skin.

Incubation period The period between exposure to a pathogen and the appearance of the first signs or symptoms.

Lethargy A lack of interest or energy to do something.

Necrosis A cell injury that can be caused by an infection, a trauma, or a toxin and results in cell death.

PCR Polymerase chain reaction.

Prophylaxis Protective or preventive treatment in the absence of a disease.

Septicemia An infection (often bacterial) of the blood.

Spore A single reproductive body, usually resistant to heat and desiccation, capable of giving rise to a new organism, characteristic of some bacteria and fungi.

WHO World Health Organization.

Zoonosis A disease that can be transmitted to humans from animals (directly or using a vector).

Introduction

Webster's dictionary defines bioterrorism as a deliberate attack using biological agents such as bacteria, viruses, or any other organisms as weapons of biological warfare. These agents are used to disrupt our way of living; spread fear; and destroy plant, animal, and human ecosystems. Biological agents can spread through the ambient air, potable water or food, and animals, and can be modified to increase their transmissibility into the environment or to make them more resistant to the antimicrobial agents. What are the different biological threats that clinicians and hospitals should be prepared to manage or should develop proactive emergency plans should a mass casualty event occur? What are the different published tools and guidelines to help the medical community to manage large numbers of sick and potentially contagious patients and the worried well visiting the emergency room at the same time? This article is intended to answer to those questions.

Bioterrorism is not an invention of the recent past. In the Middle Ages, *Yersinia pestis* was used as a biological weapon when soldiers threw plague-infected corpses over the walls of besieged cities, trying to infect and kill the enclosed population. Smallpox was used as a biological weapon in the sixteenth century. Cortez unintentionally imported smallpox to the New World and killed a large part of the Native American population. In 1754, the English intentionally used smallpox as a weapon of mass destruction, distributing infected blankets to Native Americans, decreasing the population by 50%. Additionally, in the last 50 years, five bioterrorism events have occurred, the latest episode being the 2001 release of anthrax spores through the US Postal Services. This event affected 22 people (11 pneumonia and 11 cutaneous infections – 7 confirmed and 4 suspected cases) in four states (Connecticut, Florida, New York, and New Jersey) and the District of Columbia (DC) resulting in five deaths but also in postexposure prophylaxis for more than 10 000 (Bush and Perez, 2012). Among the four other bioterrorism attacks that took place since the middle of the twentieth century, three were deliberately spread gastrointestinal (GI) pathogens in targeted populations (*Salmonella* Typhi; *Salmonella* Enteritidis; and *Shigella dysenteriae*). One involved four students exposed to an intentional massive dose of *Ascaris suum* ova leading to pulmonary symptoms and infiltrates (Ippolito et al., 2006). These examples remind us our vulnerability and the need to plan for appropriate responses to the possible agents that could be used by malicious terrorist groups or individuals.

The Classification of the Different Bioterrorism Agents

The Centers for Disease Control and Prevention (CDC, Atlanta, GA, USA) classifies bioterrorism agents into three categories (A, B, and C) according to the following characteristics: their ease of spread in the environment and the associated severity of the illness or mortality rate. Category A agents are the most threatening for public health and include organisms (or toxins) based on their ease of spread or person-to-person transmission, their high mortality rates, and potential for overwhelming impact to the public health

This article is a reprint of P. Savard, P. Maharom, T.M. Perl, Bioterrorism, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

(input of patients to the emergency department, social disruption, and public panic). The category A agents require robust public health preparedness to manage the resulting impact on public health and health-care infrastructure. Those agents considered category A are the highest priority for public health planning, implementation of surveillance, and diagnostic capacity development. Categories B and C follow with lower priorities. Category B agents are moderately easy to disseminate with moderate morbidity and lower associated mortality rates than those in category A. Finally, category C agents include emerging pathogens with the capacity of mass dissemination following laboratory modifications and are characterized by their availability, ease of production and dissemination, and potential for high morbidity or mortality.

Because specific guidelines have been especially developed mainly for the CDC category A agents, we will focus the attention of this article on these six diseases. Readers are invited to review the other articles of this encyclopedia to have more information about the diseases included in categories B and C.

CDC category A	Includes those agents that disseminate easily or where person-to-person transmission occurs and has high associated mortality rates with major public health impact. Public and social disruption may happen and require health authorities preparedness. ● Anthrax ● Botulism ● Plague ● Smallpox ● Tularemia ● Viral hemorrhagic fevers (e.g., Ebola, Marburg, Lassa, etc.)
CDC category B	Includes those agents that are moderately easy to disseminate and are associated with lower morbidity and mortality. ● Brucellosis ● Epsilon toxin of <i>Clostridium perfringens</i> ● Food safety threats ● Glanders ● Melioidosis ● Psittacosis ● Q fever ● Ricin toxin ● Staphylococcal enterotoxin B ● Typhus fever ● Viral encephalitis (alphavirus) ● Water safety threats (<i>Vibrio cholerae</i>, <i>Cryptosporidium parvum</i>)
CDC category C	Includes emerging pathogens with the capacity of mass dissemination following engineering and are characterized by their availability, ease of production and dissemination, and potential for high morbidity or mortality. ● Nipah virus ● Hantavirus

Category A Agents

Anthrax

Introduction and Microbiology

The Working Group on Civilian Biodefense identified Anthrax or the agent *Bacillus anthracis* as one of the most serious threats to a city or a country (Inglesby et al., 2002). In 1970, the World Health Organization (WHO) estimated that 50 kg of *B. anthracis* released over a city of 5 million people would probably infect 250 000 and kill 2% of the population.

Bacillus anthracis is a $4 \times 1 \mu\text{m}$ Gram-positive, facultative anaerobic or aerobic spore-forming bacillus that stains as a dark blue or violet rod usually in chains when the endospore forms with a central or subterminal location. *Bacillus anthracis* grows well on sheep blood agar and colonies are typically white to gray-white, flat with a curly tail, or a 'Medusa's head' appearance at the edge. *Bacillus anthracis* is nonhemolytic, nonmotile, catalase-positive, and classically susceptible to penicillin. The main virulence factors of *B. anthracis* are its capsule and two binary toxins called the 'edema factor' and the 'lethal factor.' The release of these toxins leads to edema, hemorrhage, and necrosis of the tissues (Inglesby et al., 2002). Epidemiologically, the bacterium is naturally found in the environment and is primarily associated with diseases in animals. It is usually transmitted to humans following contacts with infected cattle, camels, goats, or other herbivores. Hence, it was commonly called the 'wool sorter's disease' or 'ragpicker's disease' reflecting the association described with the wool of infected animals. The spores can also survive for months in the environment. Of note, as exemplified by the events in the fall of 2001, anthrax can also be acquired following malicious intention if it is used as a bioterrorism weapon (Bush and Perez, 2012).

The WHO, in collaboration with the Louisiana State University, maintains detailed data cataloging endemic anthrax in animals by country (accessible at http://www.vetmed.lsu.edu/whocc/mp_world.htm). Most countries present sporadic or low endemic animal cases but hyperendemic areas are reported in Africa (including Guinea, Sierra Leone, Liberia, Cote-D'Ivoire, Ghana, Togo, Niger, Chad, Zambia, Zimbabwe, and Ethiopia), Turkey, Tajikistan, and Myanmar.

Clinical Manifestations and Diagnosis

There are four clinical forms of the disease: cutaneous, GI, inhalational, and meningoencephalitis. All these forms could be encountered following a bioterrorist attack.

Cutaneous Anthrax

Cutaneous anthrax is the most frequent form (95%) of the disease in humans and occurs following direct skin contact when handling any contaminated source, mostly of animal origin like wool, hair, hides, or fur; the bacteria or its spores then may enter the skin through an abrasion. The incubation period varies between 1 and 12 days. The initial lesion is characterized by a painless, but typically, pruritic sore with a central vesicular or bullous lesion and peripheral edema. The central lesion further develops into an ulcer with a hemorrhagic and necrotic center followed by formation of a black eschar. If untreated, 20% of patients will die of cutaneous anthrax (Inglesby et al., 2002). When treated, the mortality rate is reduced to less than 1%.

Gastrointestinal anthrax

Gastrointestinal anthrax is a rare form of the disease (<5%) and follows consumption of contaminated fluid or undercooked infected meat and has two clinical presentations: oropharyngeal and intestinal, the latter being more frequent. The first syndrome is characterized by the development of cervical adenopathy and soft tissue edema, fever, oral lesions followed by ulceration and central necrosis after the consumption of infected food (Inglesby et al., 2002). The second form has three phases: initially, patients develop low-grade fevers, malaise, and fainting followed by mild to severe abdominal pain, nausea, vomiting, mild diarrhea, ascites, intravascular depletion, and abdominal distension. During the third phase, patients show paroxysmal abdominal pain, increasing ascites, and often shock (Kanafani et al., 2003). Surgical interventions and antimicrobial treatment may benefit those with a severe clinical presentation.

Inhalational anthrax

Inhalational anthrax follows inhalation of airborne spores from air or spores found in the fur or wool of an infected animal. It should always raise the concerns of a bioterrorist attack. The incubation period is generally 9–10 days but ranges from 2 to 98 days. The typical picture without treatment includes hemorrhagic mediastinal adenopathy and/or pleural effusions and a rapid evolution to death. As it is the case with the GI form, the inhalational anthrax can present in a two-stage fashion with an initial flulike syndrome (low-grade fever, malaise, myalgia, headache) followed by respiratory, neurologic, GI, and cardiovascular compromise (Inglesby et al., 2002). Meningitis or meningoencephalitis forms have 95% mortality whether or not the patient is adequately treated. This form of the disease is also characterized by hemorrhagic changes of the meninges due to invasion of blood and the cerebrospinal fluid (CSF) by the bacteria.

Confirmatory testing should always be performed at a reference laboratory. Suspected cultures in a clinical lab should be transferred to a biosafety level (BL) 3 laboratory for further analysis. The CDC have issued guidelines for testing clinical samples when a clinical suspicion of anthrax is raised that included culture, immunohistochemistry, serology, and polymerase chain reaction (PCR) testing. For example, in case of a cutaneous disease, the CDC recommend that samples (e.g., vesicular fluid from an unopened vesicle, swab samples from underneath the eschar, or base of ulcer) are obtained for both culture and PCR. Blood should be cultured and acute and convalescent serology obtained. Biopsy specimens are also recommended for the papule or vesicle including adjacent skin. The recommended testing analyses for inhalational or GI anthrax are available on the CDC Web site (<http://emergency.cdc.gov/agent/anthrax/lab-testing/>).

Treatment

If anthrax is suspected, treatment should be promptly initiated using intravenous treatment initially. For adult patients including pregnant women, the treatment of choice for inhalational, GI, or oropharyngeal anthrax should combine either ciprofloxacin (400 mg IV every 12 h) or levofloxacin (500–750 mg IV every 24 h) or doxycycline (100 mg IV every 12 h) with at least one more agent including clindamycin (900 mg IV every 8 h) or rifampin (300 mg IV every 12 h). Clindamycin is thought to block toxin production and rifampin penetrates well different tissues including the CSF. Other possible combination regimens include imipenem, clarithromycin, vancomycin, or chloramphenicol (Inglesby et al., 2002). Furthermore, if the strain is reported susceptible to penicillin, this agent may also be used. Cephalosporins should not be prescribed. According to some laboratory data on 53 *B. anthracis* strains isolated in Turkey, all were susceptible to ciprofloxacin, levofloxacin, tigecycline, linezolid, and vancomycin (Ortatatli et al., 2012).

Children should also be prescribed the same regimen with adjusted doses (see <http://emergency.cdc.gov/agent/anthrax/>). A switch to oral route, once the clinical presentation improves is indicated with a total duration of antimicrobials of 60 days. Steroids may be considered as adjunct therapy for those with severe edema or meningitis.

For cutaneous disease, treatment is usually 7–10 days but in a bioterrorism situation, where the risk of inhalation is greater, 60 days are also recommended with either ciprofloxacin or levofloxacin for both adults (including pregnant women) or children and doxycycline as an alternative treatment.

Infection Prevention Strategies

Inhalational anthrax is not spread from person to person and does not necessitate specific infection control practices other than the standard precautions. There is a theoretical risk of transmission to health-care personnel in case of cutaneous anthrax and gloves are

then required. In the case of an attack exposure, any person in direct physical contact with the agent containing the potential spores should readily and profusely wash the exposed skin and pieces of clothing with soap and water. Also, only those deemed directly exposed to the contaminated source would require postexposure prophylaxis. Decontamination of the environment should follow the usual hospital protocol. In some cases additional decontamination of the environment may be needed and should include an agent with activity against spores. Cases must be reported to public health authorities immediately and the laboratory should be notified when a suspected case is admitted to the hospital in order to put in place the adequate laboratory practices.

Vaccination

AVA vaccine (BioThrax) is available in the United States following a 5 dose-preexposure regimen with annual booster or a 3 dose-postexposure regimen. This vaccine is not available for the general public and is intended to at-risk people only. Preand postexposure protocols exist and the vaccine was shown effective against inhalational anthrax when combined to the right postexposure antimicrobial prophylaxis. Readers are referred to the Advisory Committee for Immunization Practices (<http://www.cdc.gov/vaccines/pubs/ACIP-list.htm>) for more details about the specific AVA vaccine recommendations.

Postexposure Prophylaxis

Given the current data on inhalational anthrax, three doses of AVA vaccine administered at time 0, 2, and 4 weeks along with 60 days of oral antimicrobial prophylaxis (ciprofloxacin or doxycycline) for those exposed to *B. anthracis* is the treatment of choice. Levofloxacin is also FDA-approved for chemoprophylaxis but safety data for therapies longer than 28 days are lacking and should be considered as a second-line choice. Penicillin G (FDA-approved) or amoxicillin (not approved by FDA) are effective but cannot be used if beta-lactamase production by the *Bacillus* strains is reported (Inglesby et al., 2002). Penicillin derivatives should be used only when susceptibility data confirm their efficacy. Other drugs including clindamycin, chloramphenicol, rifampin, and vancomycin may be considered in those patients who cannot tolerate the first- and second-line therapies. Regimens have also been developed for special population including pregnant women and children where the risks associated with anthrax must be balanced against the side effects of the drug regimen.

Botulism

Introduction and Microbiology

Botulism is a disease caused by neurotoxins produced by the bacteria *Clostridium botulinum*, and rarely by *Clostridium butyricum* and *Clostridium baratii*. *Clostridium botulinum* is a Grampositive, spore-forming, obligate anaerobe bacillus that can be found in soil and marine sediments worldwide (CDC, 1998). Botulinum toxin is one of the most lethal substances, with an LD₅₀ of 0.0001 µg kg⁻¹; as a result, 1 g of the crystallized toxin, evenly dispersed and inhaled, can kill more than 1 million people (Darling et al., 2002).

Seven different types of Botulinum toxins exist and are referred to as types A–G. Different intracellular protein targets occur for each serotype. The toxin causes flaccid paralysis of the muscles. Although spores of *C. botulinum* can survive for several hours at 100 °C, their toxins are heat labile, and can be inactivated after 5 min at 85 °C (Darling et al., 2002).

Before 1949, the case-fatality rate was approximately 60%. Mortality is lower when the disease is recognized and treated early, proper supportive and respiratory intensive care is provided, and there is an effective public health response (CDC, 1998).

Clinical Manifestations

Botulinum toxin can be introduced to the human body via the GI route (foodborne and infant botulism), the pulmonary route (inhalation botulism), and absorption through the bloodstream from infected wounds (wound botulism) (Arnon et al., 2001).

Clinical manifestations of all types of botulism are characterized by a classic triad: (1) lack of fever, (2) symmetric and descending flaccid paralysis with prominent bulbar palsies, and (3) intact sensorium. The prominent bulbar palsies may be summarized as the '4Ds': diplopia, dysarthria, dysphonia, and dysphagia (Arnon et al., 2001). Foodborne botulism may have GI symptoms such as nausea, vomiting, abdominal cramps, or diarrhea.

Foodborne Botulism

Botulism caused by the ingestion of botulinum toxincontaminated food and it is the most common type of botulism worldwide. Sources of contaminated food include improperly canned or preserved food. Among those foods, vegetables with low acid (pH > 4.6) such as beans, garlic, pepper, carrots, and corn are considered as those with the highest risk of contamination. Meat has been reported as another source of foodborne botulism including fermented foods, seal oil, salmon, and dried foods. In the United States, the toxin types represented in the 444 foodborne outbreaks from 1950 to 1996 were type A (37.6%), E (15.2%), B (13.7%), and F (0.7%). Approximately 33% were unidentified with respect to toxin type. Signs and symptoms of foodborne botulism can occur after 2–8 days following the exposure, depending on the rate and amount of toxin absorption. Average incubation period is 12–72 h after the implicated meal (CDC, 1998).

Inhalation Botulism

Aerosol dissemination of botulinum toxin can also cause the disease and may not be difficult to recognize because of a common temporal and geographical exposure among cases. Incubation period of inhalation botulism is not established. Onset of symptoms

was approximately 72 h after exposure in a few reported cases. Animal data show signs of the disease after 12–80 h of exposure (Dembek et al., 2007).

Infant Botulism

Infant botulism, while distinct from foodborne botulism, is one of the most common forms of botulism, yet it is unlikely to be linked to bioterrorism. Infant botulism develops after the ingestion of *C. botulinum* spores, not toxin, leading to *in vivo* toxin production in infants' intestines. In general, cases occurred after honey or corn syrup was fed to infants. Clinically, infant botulism starts with constipation, and is followed by neuromuscular paralysis. Disease severity is broad, and ranges from only lethargy to respiratory failure (CDC, 1998).

Diagnosis and Differential Diagnosis

Early recognition of botulism using clinical criteria is essential because a confirmatory test requires days to complete. Differential diagnosis includes polyradicular neuropathy (Guillain-Barré or Miller Fisher syndrome), myasthenia gravis, or intoxication (e.g., depressants, organophosphates, carbon monoxide, or nerve gas). Botulism can be distinguished from these diseases by a clear sensorium and its prominent cranial nerve palsies disproportionate to milder weakness and hypotonia below the neck. Epidemiological clues that include a careful travel and dietary history should be obtained from suspected patients. Contact the local public health authorities and hospital epidemiologist promptly to coordinate treatment, diagnostic needs, and the epidemiological investigation (Amon et al., 2001).

Diagnostic Laboratory

Obtain clinical samples including preantitoxin treated serum (≥ 30 ml in adult, less in children), stool, gastric aspirate, vomitus, and suspected food (if available). All clinical specimens have to be kept refrigerated after collection. In general, these tests are performed in a public health laboratory. The standard mouse bioassay is very sensitive, and detects more than 0.03 ng of botulinum toxin but the turnaround time is 1–2 days. The bioassay can also demonstrate a specific toxin (CDC, 1998).

An electromyogram with repetitive nerve stimulation at 20–50 Hz may differentiate botulism from other causes of acute flaccid paralysis. CSF analysis is usually normal in botulism (Dembek et al., 2007).

Treatment

Treatment for botulism requires supportive care and passive immunization with antitoxin. Prompt administration of antitoxin using recommended doses can neutralize circulatory botulinum toxin and minimize subsequent nerve damage (Dembek et al., 2007). Unfortunately, the antitoxin cannot reverse existent paralysis (Table 1). Skin tests should be performed prior to administering these products as there is risk of hypersensitivity reactions to the equine components.

Infection Prevention Strategies

Botulism is not transmitted by person-to-person contacts. Isolation is not necessary and standard precautions are used. After aerosolized toxin exposure, decontaminate clothing and skin with soap and water. Contaminated objects should be cleaned with 0.1% hypochlorite solution (Amon et al., 2001).

Prevention

Preexposure Prophylaxis

The pentavalent botulinum toxoid (PBT) against botulinum toxin types A–E has been used since 1959 but is not FDA approved. Because of its reactogenicity and declining of immunogenicity, PBT administration should only be considered in people who are at risk of botulism such as laboratory workers and military personnel. The CDC's current recommendation of PBT protocol requires a

Botulism: cause, effects, diagnosis, clinical and laboratory identification, and treatment modalities. *Disaster Med. Public Health Prep.* 1 (2), 122–134.

primary series of four subcutaneous injections of 0.5 ml at 0, 2, 12, and 24 weeks, followed by a booster dose at 12 months and booster doses annually, thereafter. Antitoxin titers are not needed. Research to develop newer toxoids and recombinant vaccines is ongoing (Rusnak and Smith, 2009).

Postexposure Prophylaxis

PBT is not recommended for postexposure prophylaxis. Because a study in nonhuman primates demonstrated that exposed individuals may not develop disease, asymptomatic individuals who are exposed to botulinum toxin should not receive passive immunoprophylaxis (Darling et al., 2002). Data also demonstrate that botulinum immune globulin administered within the first 24 h after a high-dose exposure to the toxin is beneficial. The risk of potential adverse effects from equine antitoxin and the expected morbidity and mortality from the disease should be weighed (Arnon et al., 2001).

Plague

Introduction and Microbiology

Bioterrorism attacks using *Y. pestis* should be considered if many cases of severe pneumonia in critically ill previously healthy adults come to medical attention. *Yersinia pestis*, the causative agent of plague, is a member of the family *Enterobacteriaceae* and is another agent of great concern given the capacity for its mass production and dissemination, its high fatality rate, and the possibility of person-to-person transmission (Inglesby et al., 2000). The Black Death is one of three historically important outbreaks caused by plague. It decimated one-fourth of the European population in the Middle Ages. Plague is a zoonotic disease that is transmitted from infected animals to humans via either the bite of an infected flea, *Xenopsylla cheopis*, direct contact with or inhalation of infected particles or rarely following ingestion of contaminated material.

Plague remains endemic among small animals in many countries in Africa, Asia, the Americas, and the former Soviet Union, even today. In 2003, WHO reported 2118 cases and 182 deaths in nine countries. Among these reports, 98.7% of cases and 98.9% of deaths occurred in Africa. Most recently, Peru reported 17 cases (4 pneumonic plague, 12 bubonic plague, and 1 septicemic plague). Infected rodents and domestic cats were the source of the outbreak (http://www.who.int/csr/don/2010_08_10/en/index.html). Hence, plague remains a credible threat and a potential agent of bioterrorism.

Clinical Manifestations

Different plague syndromes have been described: bubonic plague, septicemic plague, pneumonic plague, and meningial plague.

Bubonic Plague

The incubation period of bubonic plague is 2–8 days after the flea bite infected with *Y. pestis*. The organism initially proliferates in the regional lymph nodes. Clinical manifestations include sudden onset of fever, chills, malaise, headache, prostration, lethargy or agitation, seizures (in children), and shortly after an enlarged painful lymph node (bubo) develops in the affected region. Typically, the mass is firm, tender, and nonfluctuant and measures between 1 and 10 cm and the skin is usually warm and erythematous. The most common sites for painful lymphadenopathy include the groin, axillary, and cervical regions (Inglesby et al., 2000). In addition, GI symptoms including abdominal pain, nausea, vomiting, and diarrhea may precede the bubo formation. Of note, bubonic plague can rapidly evolve without appropriate treatment leading to shock and death within 2 or 3 days of symptom onset.

Septicemic Plague

Following the initial proliferation of organisms in the local lymph nodes, the organism can spread hematogenously. Primary septicemic plague may develop without a bubo and in this form, patients develop high fever without lymphadenopathy and can die rapidly. An inflammatory response can lead to disseminated intravascular coagulation and organ failure that precipitate death. Purpuric lesions on the trunk and limbs, associated with necrosis of acral parts of the body (finger tips, nose, and toes) are characteristic (Inglesby et al., 2000). As with bubonic plague, patients may initially present with digestive complaints.

Pneumonic Plague

Pneumonic plague develops following either hematogenous spread of the bacillus from the bubo (10% of cases) or inhalation of infectious droplets (primary inhalation pneumonia) following close contact with a case of symptomatic pneumonic plague. This disease form evolves rapidly and patients often develop septic shock and organ failure. Classic symptoms include dyspnea, tachypnea, chest pain with cough, and hemoptysis or watery sputum. Untreated, the disease is always fatal and mortality increases as the treatment is delayed (Inglesby et al., 2000). Recent cases of primary pneumonic plague can follow laboratory incidents or exposure to domestic cats with respiratory symptoms.

Meningial Plague

Meningial plague is usually a complication of untreated plague (bubonic) and manifests with symptoms of acute nervous system infections including headache, nuchal rigidity, fever, and meningismus (Inglesby et al., 2000). Cultures generally grow organisms and pleocytosis of the CSF is common. Rare GI manifestations of plague including pharyngitis can follow the ingestion of the bacillus.

Suspected clinical cases of plague should be reported diligently to the Public Health Authorities to initiate an investigation.

Diagnosis

Physicians should have a high level of suspicion when patients returning from a plague endemic zone report exposures (contact with fleas, animals, or infected people) and present with an acute febrile illness to the hospital. Elevated white blood cells and decreased platelet counts are frequent findings in the various disease forms. Blood should be cultured before antimicrobial treatment is initiated and the laboratory notified of the clinical suspicion as specimens are processed with BL2 protocols. Other specimens including bubo aspirates, sputum, broncho-alveolar lavage, pharyngeal swab, CSF, or swabs of skin lesions should be obtained if symptoms are present. *Yersinia* spp. grows well on different media used in the microbiology laboratory including brain–heart infusion broths, sheep blood agar, MacConkey agars, etc. Smears from bubo, sputum, blood, or central nervous fluid can be stained (Gram) to look for the characteristic bipolar-staining (safety pins) Gram-negative organisms. Other diagnostic methods include serologic testing (hemagglutination test, enzymelinked immunosorbent assays (ELISAs)), and PCR techniques are available in specialized laboratories.

Treatment

When the disease is suspected, cultures should be obtained immediately and antimicrobials started. Streptomycin is the treatment of choice (Inglesby et al., 2000) (7.5 mg kg^{-1} of body weight each 12 h) for 7 days. The dose should be adjusted in case of renal insufficiency and it should be used cautiously in pregnant women. Most of the patients become asymptomatic within a few days. While streptomycin is not commonly used now, gentamicin (5 mg kg^{-1} for loading dose then 1.7 mg kg^{-1} every 8 h for 10 days) or a combination of gentamicin (same doses) and doxycycline ($100 \text{ mg IV or PO every 12 h}$) for 10 days are as effective as streptomycin. Doxycycline or tetracycline can be given orally following an initial intravenous regimen using an aminoglycoside. Ciprofloxacin $400 \text{ mg IV every 12 h}$ (adjusted in case of renal insufficiency) or chloramphenicol $1 \text{ g IV four times a day for 10 days}$ are alternative agents. For pregnant women risk and benefits must be balanced but gentamicin 5 mg kg^{-1} every 24 h for 10 days has been recommended with alternative treatments using ciprofloxacin or doxycycline for 10 days.

Infection Prevention Strategies

Pneumonic plague is spread through respiratory droplets. Hence, household members and health-care workers are at increased risk of acquisition if appropriate measures are not observed. Symptomatic patients should be placed in droplet precautions (medical mask, gown, gloves, eye protection). Usually, droplet precautions can be stopped following 48 h of appropriate therapy and with clinical improvement (Inglesby et al., 2000). Contact precautions are also used for patients with bubo.

Prophylaxis is indicated for those exposed and in close contact (2 m, not using barrier precautions) as in the household, work place, or at the hospital to a symptomatic contagious patient. The preferred prophylaxis regimen is doxycycline $100 \text{ mg PO BID for 7 days}$ but some experts recommend ciprofloxacin $500 \text{ mg orally twice everyday}$ or levofloxacin $750 \text{ mg orally twice everyday for 7 days}$. The same regimens apply for pregnant women although the risk benefit to the mother child must be weighed.

Smallpox

Introduction and Microbiology

Smallpox (*Poxvirus variolae*) is a serious, contagious, lifethreatening disease caused by a brick-shaped, double-strand DNA virus in the genus *Orthopoxvirus*. It is a credible biological weapon because of its high case-fatality rate, no established definitive treatment, and its possibility of transmission via aerosols (Cleri et al., 2006). WHO declared smallpox eradicated in 1980, which led to abandonment of smallpox vaccination worldwide. With declining immunity in human populations and the lack of natural exposure to the disease, large populations are vulnerable to infection with this virus.

Clinical Manifestations

The average incubation period is 10–12 days. After the virus penetrates the respiratory epithelium, within 72 h, it is transported to regional lymph nodes by infected macrophages. Once it has replicated for 96 h in the lymphoid tissues, a second viremia develops and patients present with symptoms. Initial symptoms of the disease are nonspecific and include fever, malaise, head and body ache, and sometimes, vomiting. After 2–4 days of the symptoms, patients develop maculopapular rash that will become pustular lesions and finally scab. In the normal host, this maculopapular and vesiculopustular rash develops centrifugally (Henderson et al., 1999).

There are two major forms of smallpox: variola major and minor. Variola major is more virulent and contributes to higher case-fatality rate. This type is divided into four disease entities: ordinary (most frequent type); modified (vaccine-modified and relatively mild form); flat (malignant); and hemorrhagic (fulminate) (Cleri et al., 2006). The latter two forms are rare and more severe. Overall, the mortality of variola major is 30%. Variola minor is less common and much less severe disease. Its mortality is less than 1% (Veenema, 2003).

Smallpox needs to be distinguished from chicken pox (varicella). The clinical syndrome and febrile syndromes caused by both viruses overlap; symptoms, incubation periods, rash evolution, and rash presence on the palms and soles are similar (Cleri et al., 2006). Hence, confirmatory laboratory testing is crucial. Clinical specimens include the vesicular fluid for electron microscopic examination and viral culture that must be processed using BL4 protocols (Moran et al., 2008). Antibody testing

in patients can be measured in the convalescence period for confirmation but may not be helpful in the initial disease management.

Treatment

Treatment for smallpox is limited. No promising antiviral or immunotherapy has been proven to improve outcomes in patients with smallpox. Parenteral cidofovir is licensed for treatment of cytomegalovirus, and is effective against other viruses in the genus *Orthopoxvirus* (Moran et al., 2008). Its utility in smallpox is not known and the severity of the disease should be balanced with the drug's side effects. Supportive treatment and antibiotic therapy for superimposed bacterial infections are standard of care (Henderson et al., 1999).

Infection Prevention Strategies

The contagious period of smallpox occurs after symptoms are present. Data from observational studies have not demonstrated disease transmission during the incubation period. Viral shedding occurs in the first 10 days after patients develop the rash and is present until all scabs and crusts fall off. Smallpox can spread from person to person, primarily from infected droplet nuclei, or aerosol. Contact with the contaminated crusts, contaminated clothes, and bed linens of the patients can transmit the disease as well. It is widely acceptable that only a few virions can cause the disease (Henderson et al., 1999).

Because of infectious properties of the virus, infection control strategies include airborne and contact precautions. Patients should be isolated for both confirmed and suspected cases. Patients must be placed in negative pressure rooms and equipped with high-efficiency particulate air filtration if available. In settings with limited resources a room with large windows and extensive air movement is best. Contact precautions include the use of gloves, gowns; and fitted respirators (airborne) are also recommended. All household and face-to-face contacts must be vaccinated as soon as possible to prevent disease. Postexposure prophylaxis with vaccine is best administered within the first 4 days after exposure. In an epidemic, an emergency vaccination program is indicated for all front-line staff with a high risk of exposure including healthcare personnel working in health-care facilities that might receive patients, firemen who may handle infected bodies, or emergency management staff. An expert working group also recommended smallpox vaccination in all hospitalized patients during an outbreak setting. Those at risk of exposure with a contraindication to live vaccine may require vaccinia immune globulin (VIG) instead (Henderson et al., 1999).

Preexposure Prophylaxis: Vaccine and Its Adverse Events

Edward Jenner first developed smallpox vaccine in 1796 by inoculating the cowpox virus to a human. Since this time, the smallpox vaccine has evolved into a live attenuated virus that uses vaccinia virus, which is closely related to variola virus (Metzger and Mordmueller, 2007). Because of the eradication of smallpox and the risks of the vaccine that outweigh the benefits, the CDC do not recommend preexposure prophylaxis for general population. High-risk groups, which include laboratory workers directly exposed to smallpox virus or other virus in the genus, are still offered the vaccine (Wiser et al., 2007).

Preexposure prophylaxis is contraindicated in those with immunosuppression, HIV infection, eczema, and household or sexual contact with an individual with known contraindications. The vaccine is also contraindicated in pregnancy. The vaccine complications vary from self-limited to life-threatening conditions, such as postvaccination encephalitis, vaccinia necroform or progressive vaccinia, and eczema vaccinatum, that occur most commonly in immunocompromised hosts and household contacts (Cono et al., 2003; Table 2).

Postexposure Prophylaxis

There are no absolute contraindications for postexposure prophylaxis and the risks must be carefully weighed with the benefits. For individuals with the contraindications mentioned above who have been in close contact with smallpox patients, VIG may be given simultaneously (0.3 ml kg⁻¹ body weight) to prevent complications. In case that VIG is not available, vaccination is still useful because of higher risk of smallpox disease itself than from vaccine complications (Henderson et al., 1999).

Table 2 Complications associated with the smallpox (vaccinia) vaccine

Vaccination status	No. vaccinated	Postvaccinal encephalitis		Vaccinia necrosum		Eczema vaccinatum		Generalized vaccinia	Accidental infection	Other complications ^a
		Cases	Fatalities	Cases	Fatalities	Cases	Fatalities			
Primary vaccination	5.6 million	16	4	5	2	58	0	131	142	66
Revaccination	8.6 million	0	0	6	2	8	0	10	7	9
Contacts	Unknown	0	0	0	0	60	1	2	44	8

^aErythema multiforme, painful primary take, bacterial superinfection, miscellaneous rashes, and burns.

Adapted from Lane, J.M., Ruben, F.L., et al., 1969. Complications of smallpox vaccination, 1968. N. Engl. J. Med. 281 (22), 1201–1208.

Decontamination

Vaccinia virus has been used as a model with smallpox properties in certain circumstances. The virus can be destroyed relatively easily in the settings of high temperatures and humidity. For example, the virus is killed when exposed to temperatures of 31.5–33.5 °C, and 80–83% humidity for at least 6 h. Contaminated laundry used by patients should be autoclaved or laundered in hot water with bleach (0.05–1% sodium hypochlorite) (Kumar et al., 2010). Disinfectants currently used in hospitals, such as hypochlorite and quaternary ammonium compounds, are optimal for decontamination (Henderson et al., 1999).

New Vaccine Development

The search for new smallpox vaccines and formulation is being investigated actively because of the limitations in the existing vaccine and possible use of smallpox as bioweapon (Metzger and Mordmueller, 2007).

Tularemia

Introduction and Microbiology

The fifth member of CDC category A bioterrorism organisms is *Francisella tularensis*, the causative agent of tularemia. Tularemia is a zoonosis and transmission to humans occurs when a person is exposed to diseased animals or intentional spread. Tularemia has been included as a potential agent for years with modern beginnings in the United States biological warfare program in the 1950s and 1960s. Many clinical manifestations and infection routes are described (see below) but according to The Working Group on Civilian Biodefense, aerosolization would be the most likely method of spread in case of an intentional release (Dennis et al., 2001). The attack rates of aerosolized *F. tularensis* (82.5%) and its case mortality rate (6.2%) render the organism suitable for a large-scale attack.

The organism is a small, pleomorphic aerobic Gram-negative coccobacillus that is catalase and oxidase positive. Importantly, in the laboratory, most of the strains do not grow on blood sheep or MacConkey agar because the organism requires cystine or cysteine. Chocolate agars, thioglycolate broth, or Thayer-Martin medium are more suitable in order to isolate the bacteria. Two species of *Francisella* have been described (*F. tularensis* and *F. philomiragia*) and *F. tularensis* includes four subspecies (*F. tularensis* subsp. *tularensis*; *F. tularensis* subsp. *holartica*; *F. tularensis* subsp. *Novicida*; and *F. tularensis* subsp. *mediaasiatica*). The most common are the subspecies *tularensis* (mainly seen in North America) and *holartica*.

Clinical Manifestations and Diagnosis

Sporadic cases of tularemia are encountered in the Northern Hemisphere following contact with infected animals (rabbits, hares, muskrats, beavers, squirrels) or infected ticks but transmissions through aerosols, contaminated water, and animal bites are reported. Increased risk of infection has been reported among those in close contact with potentially infected animals including farmers, veterinarians, hunters and trappers, landscapers, laboratory workers, and meat handlers (Dennis et al., 2001).

There are six classical clinical presentations. The different forms are glandular (enlarged loco-regional lymph nodes without cutaneous lesions), ulceroglandular (adenopathy with a necrotic ulcer), oculoglandular (painful conjunctivitis following direct inoculation in the eye or aerosolization associated with painful adenopathy in the preauricular, submandibular, or cervical regions), oropharyngeal (exudative pharyngitis or tonsillitis following swallowing of contaminated food, water, or droplets), typhoidal (a febrile illness not fitting in the other categories), and pneumonic (pneumonia) (Dennis et al., 2001). The syndromes may overlap in symptoms on presentation and manifestations.

The incubation period ranges from 1 to 21 days with most of the cases occurring 3–5 days after exposure. Usually the onset of the first symptoms is an influenza-like initial presentation (fever, headache, chills, malaise, and fatigue) with cough, sore throat, and myalgias. Abdominal pain, vomiting, and diarrhea may also occur. Disease can progress and acute renal failure, rhabdomyolysis, hepatitis, disseminated intravascular coagulation can develop.

Laboratory diagnosis relies on culturing the organism from blood, sputum, wound, lymph nodes, or pleural fluid. Suspected cultures should be manipulated in a BL3 cabinet to avoid transmission to laboratory personnel. If the appropriate facilities are not available, the suspected strain should be sent to a reference laboratory for further analysis. The final identification can be confirmed using slide agglutination, antisera, direct fluorescent antibodies, or cell wall fatty acid composition analysis. PCR has also been developed for use on human specimens (including blood and skin lesions biopsies). These rapid identification systems are likely important in an event of mass terrorism. Serologic studies are also available but take longer for results (2 weeks) and are not suitable in this context.

Treatment

Treatment relies on the use of aminoglycosides: streptomycin (1 g IM every 12 h) or gentamicin (5 mg kg⁻¹ IV every 24 h) are the preferred agents and should be administered for 10 days. Ciprofloxacin, doxycycline, or chloramphenicol are alternative agents but should be administered for 14–21 days (Dennis et al., 2001). Pregnant women should receive the same regimens as other adults and aminoglycosides, ciprofloxacin, and doxycycline are also recommended for children following mass exposure.

Infection Prevention Strategies

Standard precautions are indicated. There is no human-to-human transmission of the disease although outbreaks may occur following exposure to a common contaminated source or intentional large-scale release (Dennis et al., 2001). Mainly, infection

prevention interventions should target assuring that specimens are appropriately handled (safety cabinets) and prophylaxis administered if needed. Autopsy personnel are also at increased risk of exposure to aerosolized infected tissues and should use contact and droplet precautions when a case is suspected. Contaminated surfaces in the laboratory can be cleaned using a fresh solution of 10% chlorine (bleach solution).

Prophylaxis

Following exposure to tularemia, patients should be offered a prophylaxis with either doxycycline (100 mg PO every 12 h) or ciprofloxacin (500 mg PO every 12 h) for 14 days (Dennis et al., 2001). Attempts to develop a reliable vaccine against *F. tularensis* infection began in the early 1930s. A live vaccine was developed in the 1950s but is no longer available and regimens based on antimicrobial prophylaxis are the only available at this point.

Viral Hemorrhagic Fevers

Introduction and Microbiology

Viral hemorrhagic fever (VHF) generally refers to a syndrome characterized by acute febrile illness with bleeding diathesis and is caused by several families of small RNA viruses with lipid envelopes. In 2000, these viruses were classified as category A based on their ability to pose a significant threat to public health because of their ease of dissemination or transmission, high mortality and morbidity, the lack of an effective vaccine, feasibility of large-scale production, and significant impact on public health including panic, social, and economic disruption (Borio et al., 2002). In this section, we focus on hemorrhagic fever viruses in four families including Filoviridae (Ebola, Marburg), Arenaviridae (Lassa, New World Arenaviridae), Bunyaviridae (Rift Valley fever), and Flaviviridae (yellow fever, Omsk hemorrhagic fever, Kyasanur forest disease). Crimean-Congo hemorrhagic fever and dengue virus may produce high morbidity and mortality but they are not mentioned in this article because of technically difficult to produce in large-scale amount that could be widely distributed.

Clinical Manifestations

VHF presents with nonspecific symptoms including an abrupt onset of fever, headache, myalgia, nausea, vomiting, diarrhea, and followed by maculopapular rash, particularly involving the trunk. Findings may include hypotension, relative bradycardia, conjunctivitis, and pharyngitis. A bleeding diathesis with petechiae, ecchymosis, hemoptysis, melena, conjunctival hemorrhage, and disseminated intravascular coagulopathy may develop later (Borio et al., 2002; Moran et al., 2008). The causative agent depends on the geographic distribution of the virus and its host. The average incubation period is 2–21 days (Table 3). In areas where these diseases are not endemic, a strong index of suspicion is needed and a bioterrorism attack should be suspected. Other organ involvement may suggest a particular viral etiology. For example, jaundice is typical in Rift Valley fever and yellow fever; (Moran et al., 2008) moreover, Lassa fever may present with leukocytosis instead of the leukopenia associated with other viruses (Pigott, 2005). No pathognomonic laboratory findings distinguish the causes of the disease.

VHF agents should be manipulated in BSL-4 containment facilities. Testing methods include antigen detection by antigen-capture ELISA, IgM antigen detection by antibodycapture ELISA, RT-PCR, and viral isolation (Pigott, 2005).

Treatment

Supportive treatment with careful maintenance of fluid and electrolyte balance, blood pressure, along with early recognition and treatment of disease complications (e.g., DIC, acute renal failure) are the foundation of VHF treatment. No antiviral agent is

Table 3 Hemorrhagic fever viruses and their distribution and disease characteristics

Virus	Vector in nature	Natural distribution	Incubation period (days)	Person-to-person transmission	Mortality (%)	Treatment
Ebola	Unknown	Africa	2–21	Yes	50–90	Supportive
Marburg	Unknown	Africa	2–14	Yes	23–70	Supportive
Lassa Fever	Rodent	West Africa	5–16	Yes	15–20	Ribavirin, supportive
New World Arenaviruses	Rodent	Americas	7–14	Yes	15–30	Ribavirin, supportive
Rift Valley Fever	Mosquito	Africa, Saudi Arabia, Yemen	2–6	No	<1	Ribavirin, supportive
Yellow Fever	Mosquito	Africa, Tropical Americas	3–6	No	20	Supportive
Omsk Hemorrhagic Fever	Tick	Central Asia	2–9	No	0.5–10	Supportive
Kyasanur Forest disease	Tick	India	2–9	No	3–10	Supportive

Adapted from Borio, L., Inglesby, T., et al., 2002. Hemorrhagic fever viruses as biological weapons: medical and public health management. *J. Am. Med. Assoc.* 287 (18), 2391–2405.

available for the treatment of the disease (Borio et al., 2002). Oral ribavirin has demonstrated some antiviral activity against Arenaviridae and Bunyaviridae in limited human studies. Ribavirin is in a category class X that is contraindicated in pregnant patients. Hence, the risk of fetal toxicities and maternal mortality must be weighed (Bausch et al., 2010). There is currently no indication for corticosteroids. Aspirin and nonsteroidal anti-inflammatory drugs, and intramuscular administration of drugs are contraindicated because of potential bleeding complications (Borio et al., 2002).

Infection Prevention Strategies

Health-care-associated infections have been associated with reuse of blood-contaminated medical items and among healthcare workers who have provided patient care without appropriate barriers to prevent exposure to blood and other body fluids. Person-to-person transmission has been recognized in filoviruses and arenaviruses. Airborne transmission does not readily occur except in Lassa fever where the index patient had severe pulmonary involvement (Monath, 1975).

Standard precautions with contact and droplet isolation are recommended for suspected VHF cases. Hospitalized patients should be placed in private rooms. Airborne precautions can be used in suspected cases with severe pulmonary symptoms, or who undergo aerosol-generating procedures (such as aerosolized or nebulized medication administration). Barrier methods include gloves, impermeable gown, face shields, and goggles for eye protection. Additional barriers (e.g., plastic aprons, leg and shoe coverings) may be needed depending on the likelihood and magnitude of contact with body fluids. The Working Group on Civilian Biodefense also recommended using of double gloves in all suspected VHF patients. Nonessential health-care personnel and visitors should be restricted from entering the room of the patients (Borio et al., 2002).

Environmental Decontamination

Environmental surfaces or inanimate objects contaminated with blood, and other body fluids, secretions, or excretions (including vomitus) should always be decontaminated. In general, household bleach in a dilution of 1:100 should be used, whereas 1:10 dilutions should be used only in grossly soiled surfaces. Medical wastes (e.g., feces) can be disposed in the sanitary sewer following local sewage disposal requirement, while contaminated solid medical waste (e.g., needles, syringes) should be managed according to existing local and state regulations. Alternatively, on-site decontamination in an incinerator or a gravity-displacement autoclave can be used (CDC, 2005).

Postmortem Practices

Disease transmission in Ebola outbreaks has occurred after contact with cadavers hence standard precautions, and isolation as described above should be used in postmortem situations Prompt burial or cremation with minimal handling of bodily secretions is recommended (Borio et al., 2002).

Postexposure Prophylaxis

Use soap and water and wash aggressively when percutaneous or mucocutaneous exposures to contaminated blood or body fluids of suspected VHF patients occur. There are no data supporting the use of ribavirin preemptively. Exposed individuals should be placed under medical surveillance. Early recognition of any symptoms such as fever (101 °F, or 38.3 °C), and prompt administration of ribavirin are recommended (Borio et al., 2002). No effective vaccines for these viruses are currently available (Pigott, 2005; Hartman et al., 2010).

Hospital Preparedness

Health-care practitioners are the primary source of reporting potential cases of bioterrorism to local health departments. Health departments must scrutinize disease patterns and diagnostic clues that suggest an unusual infectious diseases outbreak (CDC, 2001). Indications suggesting a possible intentional release of a biologic agent include: (1) an unusual temporal or geographic clustering of illness or a large number of patients presenting with clinical signs and symptoms that suggest an infectious disease outbreak, (2) an unusual age distribution for a disease, or (3) a large number of cases of acute flaccid paralysis with prominent bulbar palsies. Because bioengineered pathogens may have unusual or unexpected characteristics, and may not be detected by existing assays, outbreaks with unexpected or unusual clinical or epidemiologic characteristics should be pursued with added urgency (Ippolito et al., 2006). They may be considered the source of previously unidentified pathogens.

Syndromic surveillance activities for health-care providers can include using International Classification of Diseases that may facilitate implementing disease prevention and control strategies (CDC, 2003). Of note, because coding must occur, this strategy alone may delay the identification of a bioterrorism event. These syndromes are listed as follows:

1. *Botulism-like syndrome* defined as acute condition, mainly neurological involvement that may represent exposure to botulinum toxin (e.g., lateral rectus palsy, diplopia);
2. *Hemorrhagic illness* defined as specific diagnosis, acute condition with multiple organ involvement and acute blood abnormalities that may be consistent with exposure to any virus that causes VHF (e.g., yellow fever, Ebola, dengue, Crimean-Congo);
3. *Lymphadenitis* defined as acute regional lymph node swelling and/or infection consistent with a bubo associated with *Y. pestis* infection;
4. *Localized cutaneous lesion* (resembling cutaneous anthrax, or tularemia) includes acute localized edema and/or cutaneous lesion/vesicle, ulcer, eschar, or specific diagnosis of localized cutaneous lesion/ulcer consistent with cutaneous anthrax or tularemia;

5. *Gastrointestinal syndrome* defined as acute infection of the upper and/or lower GI tract, both specific (e.g., *Salmonella*) and nonspecific symptoms;
6. *Respiratory syndrome* defined as acute infection of the upper and/or lower respiratory tract, including acute specific diagnosis (e.g., pneumonia due to influenza), acute nonspecific diagnosis (e.g., sinusitis), and acute nonspecific symptoms (e.g., shortness of breath, cough);
7. *Neurological syndrome* defined as acute neurological infection of the central nervous system (CNS) that includes specific diagnosis of acute CNS infection (e.g., pneumococcal meningitis), acute nonspecific diagnosis (e.g., meningitis not otherwise specified), and acute nonspecific symptoms (e.g., meningismus);
8. *Rash* (resembles smallpox) defined as acute condition that may present as consistent with smallpox, specific diagnosis of acute rash (e.g., smallpox), and acute nonspecific diagnosis of rash compatible with infectious diseases (e.g., viral exanthem);
9. *Specific infection* defined as acute infection of known cause not covered in syndromes listed above, includes septicemia of known bacteria, other febrile illnesses (e.g., scarlet fever);
10. *Fever* defined as acute potentially febrile illness of origin not specified;
11. *Severe illness or death potentially due to an infectious disease* defined as acute onset of shock or coma from potentially infectious etiology.

Challenges in Bioterrorism and Mass Casualty Preparedness

Emergency departments would be among the first responsible health-care entities affected after a biological attack. Most hospitals have emergency response plans for responding to chemical, biological, nuclear, and explosive incidents. Written protocols to encounter rapid, mass influx of patients who may have been exposed to biological hazard have to be addressed, and drilled with other local health-care facilities and their communities (Vinson, 2007). Health-care personnel have to be educated and trained for their roles in such events (Ippolito et al., 2006). Moreover, those who have no clinical responsibilities, or patient contacts may be needed for support and should be assigned positions in the situation. Resources for mass casualty to avoid spreading of harmful pathogens, such as personal protective equipment, have to be available (Grow and Robinson, 2003). Hospital preparedness for bioterrorism, along with other mass casualty emergency plans, should be encouraged in all health-care facilities, both in metropolitan and nonmetropolitan areas for proper management in biological attacks (Beam et al., 2010).

Conclusion

Political conflicts and changing approaches to these conflicts globally make biological attacks still be possible. Bioterrorism preparedness is essential and requires that health-care professionals be engaged. New challenges in preparedness include the need for using resources efficiently and effectively and should be balanced by economic constraints. Restrictions in funding from research budgets may affect drug or vaccine development for the potential agents associated with bioterrorism. Although some difficulties exist, fundamental disease preparedness can be applied following international, national, and local health authority recommendations. Awareness of health-care personnel for changing disease patterns or syndromes, and preparedness of mass casualty for all hazardous materials are imperative. Hospital and healthcare facility roles are a priority for bioterrorism emergency response planning.

Glossary

Bacteriocin A peptide produced by bacteria, with an antimicrobial activity toward bacterial species closely-related or non-related to the producer bacterium.

Biopreservation The most commonly used definition has been proposed by Michael E. Stiles in 1996 as “Biopreservation refers to extended storage life and enhanced safety of foods using the natural microflora and (or) their antibacterial products”.

Coding sequence Portion of a gene that is transcribed into a messenger RNA and translated into a protein.

Contig A set of overlapping DNA sequences (reads) that together represent a consensus region of DNA.

Genome The collection of an organism's entire genetic information, organized in genes. In bacteria the genome is most of the time constituted by a single chromosome and sometimes plasmids, the number of which varies depending on strains.

Genomics Science that studies all genes in an organism for analyzing their physical structure and organization (structural genomics) as well as the function of genes, their regulation mode, and their interactions (functional genomics or post-genomics).

Microbial spoilage Defect of the organoleptic properties of a food product including aspect, texture, color, odor, and flavor resulting from microbial growth and metabolism with the production of molecules (volatile compounds, pigments, gas, exopolysaccharides. . .).

Microbiota All microorganisms that typically inhabit a particular environment (here the food environment) considered as a group.

Operon A functional unit of DNA containing a cluster of genes controlled by a single promoter. The genes are transcribed together into a messenger RNA.

Peptidoglycan Also called murein, is an essential and specific component of the bacterial cell wall preserving cell integrity and located on the outside of the cytoplasmic membrane of bacteria.

Psychrotrophic Ability of microorganisms to grow at 0°C. Their maximum growth temperature is above 20°C. They are widespread in natural environments and in foods.

Scaffold A set of non-contiguous series of oriented genomic sequences or contigs separated by gaps of known length but of unknown sequence.

Taxonomy Classification and description of living organisms. It includes naming and defining of species, and collecting data about their biology (phenotypic, genotypic characteristics), biogeography, and ecology).

Abbreviations

BA	biogenic amines
CDS	coding sequence
CFU	colony forming unit
MAP	modified atmosphere packaging
STAA	streptomycin-thallos acetate-actidione
VOC	volatile organic compound
VP	vacuum packaging

Introduction

The genus *Brochothrix* belongs to the *Listeriaceae* family which encompasses only two genera: *Listeria* and *Brochothrix*. To date, in the *Brochothrix* genus only two closely related species have been described. *Brochothrix thermosphacta* has been first isolated from pork sausages (McLean and Sulzbacher, 1953) and *Brochothrix campestris* from grass and soil (Talon et al., 1988). Although, these two species are non-pathogenic, *B. thermosphacta* gained a scientific interest because of its implication in the spoilage of meat and seafood products. Indeed, *B. thermosphacta* is a psychrotrophic and ubiquitous bacterium that has been reported as present in various meat and seafood products stored at cold temperatures, and as responsible for the production of undesired off-odors such as

This article is a reprint of Nassima Illikoud, Emmanuel Jaffrès, Monique Zagorec, *Brochothrix thermosphacta*, *Reference Module in Life Sciences*, Elsevier, 2018.

cheesy or buttery odors (Rattanasomboon et al., 1999; Ercolini et al., 2006; Russo et al., 2006; Casaburi et al., 2015). In the case of meat, *B. thermosphacta* was reported as the dominant spoiler of products stored under vacuum packaging (VP) or modified atmosphere packaging (MAP) (Gill and Newton, 1977; Gill, 1983).

Food spoilage consists in any change of a food product leading to its rejection based on sensory characteristics (Gram et al., 2002). Food spoilage can result from physical damages or chemical and enzymatic reactions, but microbial growth and the resulting microbial metabolic activities are the major causes of food spoilage. Although spoiled foods may be not dangerous for human consumption, they are rejected by the consumer or earlier in the food production chain because they do not fit with quality standards. Therefore spoilage has important economic and ecological consequences. Indeed, one third of food produced for the human consumption is lost or wasted every year (Gustavsson et al., 2011) and part of losses are the consequence of microbial spoilage. All types of food can be concerned by microbial spoilage, but meat and seafood products are recognized as the most perishable ones due to their near neutral pH, water content, and abundance of nutrients essential for the growth of various microorganisms (Gram et al., 2002). Several studies showed that bacteria are the dominant spoilage microorganisms of meat and seafood (Gram et al., 2002). Microbial spoilage may appear as a visible bacterial growth, as changes in the texture, aspect, or as off-odor and off-flavor development (Gram et al., 2002). It is a complex process to which many bacteria can contribute. The food microbiota and its dynamics during the shelf life is affected by the nature of the food matrix (pH, water activity, and chemical composition), the stabilization process (cooking, smoking, drying, salting...), the hygienic conditions during the processing, and the packaging and storage conditions from the distribution of the food product until its consumption (Borch et al., 1996; Samelis et al., 1998, 2000a). Although many preservation methods have been developed to enhance the storage stability and maintain quality of foods for extended periods, excessive amounts of foods are lost every year due to microbial spoilage (Gustavsson et al., 2011).

Thus understanding the behavior of *B. thermosphacta* during food production and storage and the mechanisms responsible for its spoilage activity should contribute to find solutions for avoiding its presence or development in perishable meat and seafood products. This review focuses on the characteristics of this species, its role in food spoilage, and some strategies for fighting it in the food industry.

Taxonomy History

B. thermosphacta first isolated from pork sausage (Sulzbacher and McLean, 1951) was initially named *Microbacterium thermosphactum* (McLean and Sulzbacher, 1953). However, the same authors already mentioned notable discrepancies in the cell morphology between *M. thermosphactum* and the type species of the genus *Microbacterium lacumin*. Later studies confirmed the differences in the morphology and noted other dissimilarities especially in enzymology and protein profiles, in the DNA base composition and in peptidoglycan structure (Stackebrandt and Jones, 2006). Moreover, *M. thermosphactum* isolates formed a distinct cluster sufficiently distant from other species of the genus *Microbacterium* and from the closest Gram-positive genera (Stackebrandt and Jones, 2006). Consequently, this species was reclassified to a new genus *Brochothrix* and renamed as *B. thermosphacta* and first placed in the *Lactobacillaceae* family (Sneath and Jones, 1976). Thereafter, bacteria of the genus *Brochothrix* were found to be phenotypically closer to those of the genus *Listeria* than to those of *Lactobacillus* and were therefore moved to the *Listeriaceae* family (Sneath and Jones, 1986). The phylogenetic relationship of *B. thermosphacta* with *Listeria monocytogenes* was later reinforced by the results of a study analyzing the 16S rRNA sequence of the two species (Ludwig et al., 1984). In 1988, the isolation and description of a new species belonging to *Brochothrix*, *B. campestris* (Talon et al., 1988) confirmed the genus and its classification in the *Listeriaceae* family. To date it encompasses two species: *B. thermosphacta* (type strain ATCC 11509/DSM 20171) and *B. campestris* (type strain ATCC 43754/DSM 4712), which are highly related as their 16S rDNA sequences share 99.3% identity (Stackebrandt and Jones, 2006). Recently, the *rpoB* gene sequence, encoding the beta subunit of the RNA polymerase, appeared as a powerful tool for bacterial identification and phylogenetic analyses, especially for studying closely related isolates. Alignments of *rpoB* gene sequences have been reported to enable resolution at the species and subspecies levels (Adékambi et al., 2009). Additionally, it has been reported that *rpoB* gene sequencing provided higher discriminating power than 16S rRNA gene sequencing (Adékambi et al., 2009). We have drawn a phylogenetic tree based on the alignment of *rpoB* gene sequences from 12 *B. thermosphacta* genomes and from the unique *B. campestris* genome described to date. *Listeria* species were used as an outgroup (Fig. 1). The resulting tree confirms that *B. campestris* is located on a separate branch.

Characteristics and Ecology of *B. thermosphacta*

Habitat

The natural habitat of *B. thermosphacta* is not fully known. Indeed, initially isolated from pork sausage and considered as a psychrotrophic bacterium responsible for the spoilage of meat products, it did not attract the attention of microbiologists from other fields. In addition, its successive reclassifications mentioned above may have contributed to misidentification of some isolates. Nevertheless other possible sources of *B. thermosphacta* have been reported such as soil and feces (Gardner, 1966). More recently, it has been also isolated from a wide variety of food of animal origin *i.e.* meat from mammals and birds, seafood, milk and dairy products (Stackebrandt and Jones, 2006). Moreover, *B. thermosphacta* was described omnipresent along the production chain of beef meat, from the animal to the final product. It was isolated from beef carcasses, animal skin and rumen, walls, equipment of slaughterhouses, processing plants, hands of manipulators, and ambient air of chilling rooms (Nychas et al., 2008). It is therefore

Fig. 1 Phylogenetic tree of the *rpoB* gene from *B. thermosphacta* and *B. campestris*. The *rpoB* gene sequences were retrieved from GenBank (<http://www.ncbi.nlm.nih.gov>); MAFFT alignment was performed using Geneious software R9; The phylogenetic tree was drawn with FastTree 2.1.5 then visualized with FigTree (v1.4.3); *rpoB* gene sequences from different species of the genus *Listeria* were used as outgroup species.

possible that this species lives in a wide range of habitats but has been found only in some environments where it was systematically searched, or in which it can be selected as growth conditions are optimal, such as cold temperatures and nutritious meat matrixes.

B. thermosphacta has been isolated from food, even in the absence of detectable spoilage (Nychas et al., 2007; Liang et al., 2012). Because of its ubiquitous and psychrotolerant nature, *B. thermosphacta* is frequently found as a dominant spoiler bacterium of a wide range of foodstuffs stored at low temperature. It has been identified as the emblematic bacterial species among the microbiota of 8 spoiled meat and seafood products stored at low temperature (Chaillou et al., 2015). Indeed, it has been associated to beef, veal, pork, and poultry spoiled meat (Rattanasomboon et al., 1999; Samelis et al., 2000b; Sakala et al., 2002; Bohaychuk and Greer, 2003; Vasilopoulos et al., 2008; Ercolini et al., 2011; Liang et al., 2012; Nieminen et al., 2012; Dias et al., 2013; Delhalle et al., 2016; Piotrowska-Cyplik et al., 2017) and seafood products (Drosinos and Nychas, 1996; Drosinos et al., 1997; Mejlholm et al., 2005; Jaffrès et al., 2011; Nosedà et al., 2012; Parlapani et al., 2014). In most of these reported cases, *B. thermosphacta* numbers in the spoiled food had reached levels above 7 log CFU g⁻¹.

B. thermosphacta commonly belongs to aerobic microbiota of chilled meats and is a specific spoiler of meat stored under MAP and VP (Dainty and Mackey, 1992; Nychas et al., 2007, 2008; Vasilopoulos et al., 2008; Ercolini et al., 2011; Remenant et al., 2015; Piotrowska-Cyplik et al., 2017).

General Phenotypic Description of the Species

Strains belonging to the genus *Brochothrix* are Gram positive, non-spore forming, non-motile regular unbranched rods (0.6–0.8 µm diameter and 1–2 µm long) that occur singly or in pairs. Unlike *B. campestris*, *B. thermosphacta* can arise in short chains or in long filamentous chains. In old cultures, the cell morphology of this bacterium changes from rod to coccoid but cells resume the rod form when subcultured in a suitable culture medium (Stackebrandt and Jones, 2006). *Brochothrix* sp. are aerobe and facultative anaerobe, catalase positive, and oxidase negative. These bacteria can grow at temperatures ranging from 0 to 30°C with an optimum growth between 20 and 25°C (Stackebrandt and Jones, 2006). The optimum pH for growth is pH 7.0, but *B. thermosphacta* is able to grow within the pH range from 5 to 9.

Glucose is the preferred carbon source used by *B. thermosphacta* in meat (Gill and Newton, 1977). In the IMViC tests (indole, methyl-red, Voges-Proskauer, and citrate) used for differentiating bacterial isolates, the species is considered as methyl-red and

Voges-Proskauer positive meaning ability to mixed acid fermentation and production of 3-hydroxy-2-butanone (acetoin) and 2,3-butanediol. Its metabolism is influenced by dioxygen and carbon dioxide contents in the atmosphere. Under aerobic conditions, 3-hydroxy-2-butanone (acetoin) and 2,3-butanedione (diacetyl) are the major metabolites produced from the consumption of glucose, and also free fatty acids as isobutyric and isovaleric acids which result from valine and leucine consumption at limiting concentrations of glucose (Dainty and Hibbard, 1980). In the absence of O₂, *B. thermosphacta* produces mainly L-(+)-lactic acid and ethanol (Dainty et al., 1985; Pin et al., 2002). When glucose is depleted, glycerol appears to be an alternative carbon source for growth (Macaskie et al., 1984). Nitrate is not reduced to nitrite by *B. thermosphacta* and this species does not appear to have a nitrite reductase system (Collins-Thompson and Rodriguez-Lopez, 1980; Holley, 2014). Indole and H₂S are not produced by *B. thermosphacta* (Stackebrandt and Jones, 2006).

Information about lipolytic and proteolytic activities of *B. thermosphacta* is scarce and remains ambiguous. Several studies reported that the optimal temperature for production of lipases by this species is 20°C (Papon and Talon, 1988; Braun and Sutherland, 2004; Nowak and Piotrowska, 2012). Nevertheless (Nowak et al., 2012) found that most *B. thermosphacta* strains showed a lipolytic activity at 25°C and only some at 4°C, while (Casaburi et al., 2014) did not observe any lipolytic activity from strains neither *in vitro* nor in meat. These contradictory results may be explained by the different *B. thermosphacta* strains used by these authors and suggest important intra-species diversity.

Factors Affecting Growth of *B. thermosphacta*

Various parameters are used to prolong the shelf life of food by diminishing microbial growth. These include the use of various MAP conditions (varying the O₂, CO₂ and N₂ ratios), storage at low temperature, addition of ingredients such as salts (especially in fermented and cured meat or in salted fish products), but also preservatives such as nitrite and sodium lactate. The growth of *B. thermosphacta* on meat and seafood products is highly affected by such abiotic factors (Hitchener et al., 1979; Blickstad, 1983; Labadie, 1999; Pin et al., 2002; Nychas et al., 2008). Table 1 summarizes the main effects of various factors on the growth of *B. thermosphacta* recorded from the literature.

Isolation and Identification Tools

Methods developed for isolating *B. thermosphacta* have been mainly devoted to its recovery from meat products. A selective medium has been designed and is still routinely used (Gardner, 1966, 1985). This so-called STAA medium contains streptomycin, thallium acetate, and actidione. *B. thermosphacta* is resistant to high concentrations of streptomycin-sulfate, which inhibits other Gram-positive and most Gram-negative bacteria. Thallium acetate inhibits most yeast species as well as many facultative aerobic and anaerobic microorganisms. The incorporation of actidione (cycloheximide) inhibits yeast and filamentous fungi (Gardner, 1966). Standard ISO norm 13722:1996 reports a colony-count technique for enumerating *B. thermosphacta* from meat products by plating on the selective medium STAA followed by incubation of the plates at temperatures ranging from 22°C to 25°C during 48 hours. Further tests may be necessary to check the colonies selected on STAA plates, such as an oxidase test for differentiating *B. thermosphacta* from some *Pseudomonads* that can also grow on this medium. Indeed, although the medium preferentially selects *B. thermosphacta*, a number of other bacterial species can also grow on it (Gardner, 1966).

Table 1 Abiotic factors encountered in meat products and their influence on growth of *B. thermosphacta*

Factor	Effect on <i>B. thermosphacta</i> growth	Reference
Gas composition of the atmosphere	Presence of O ₂ improves growth	Samelis et al. (2000a) Argyri et al. (2011)
	High level of CO ₂ is not inhibitory as long as O ₂ is present	Samelis et al. (2000a) Koutsoumanis et al. (2006) Asensio et al. (1988) Lopez-Galvez et al. (1995)
Temperature	Growth is favored at low temperature (0 and 5°C)	Argyri et al. (2011) Koutsoumanis et al. (2006)
pH	Growth is inhibited at low pH	Blickstad (1983)
Glucose	Increasing concentrations improve growth	Macaskie et al. (1984) Nychas et al. (2008)
NaCl	Growth still possible with 8–10%	Collins-Thompson and Rodriguez-Lopez (1980)
Nitrate	Growth inhibition by nitrate, more important inhibition in combination with low pH and low temperature	Talon et al. (1988)
Nitrite	Combination of low pH+low temperature+nitrite, increase the growth inhibition	Collins-Thompson and Rodriguez-Lopez (1980)
Sodium lactate	Levels reduced by sodium lactate in acidified chicken meat model (pH=5.0) stored at 22°C	Lemay et al. (2002)

Table 2 Main characteristics that differentiate *Brochothrix* spp. from phylogenetically close genera

Characteristics	<i>Brochothrix</i>	<i>Listeria</i>	<i>Carnobacterium</i>	<i>Lactobacillus</i>
Growth at 35°C	—	+	+	+
Growth on STAA agar	+	—	—	—
Motility	—	+	—	—
Catalase activity	+	+	—	—
GC content (%)	36–38	36–42	33–37	32–53

Both phenotypic and genotypic methods can contribute to a further fast screening of colonies isolated on STAA medium. Some key tests for the phenotypic identification of new isolates of *Brochothrix* spp. have been traditionally used such as Gram staining, detection of catalase activity, and assessment of growth at different temperatures. Table 2 summarizes the main characteristics that differentiate *Brochothrix* from other non-sporulating Gram-positive bacilli that can contaminate the same food matrices (Stackebrandt and Jones, 2006).

However, the above mentioned tests do not enable the discrimination of *B. thermosphacta* from *B. campestris*. Those can be differentiated by their ability to grow in media containing 8%–10% NaCl or 0.05% of potassium tellurite, as *B. thermosphacta* can grow on these media whereas *B. campestris* cannot. Moreover, unlike *B. thermosphacta*, *B. campestris* is able to hydrolyze hippurate and produces acids from rhamnose (Stackebrandt and Jones, 2006).

Recently, molecular techniques have been widely applied for detecting and typing foodborne pathogens and spoilers (Van Der Vossen and Hofstra, 1996; Scheu et al., 1998; Böhme et al., 2014; Ceuppens et al., 2014). For example, 16S rRNA gene sequencing is the most commonly used method for studying bacterial phylogeny and taxonomy. However, although it is a powerful tool for many genera and species, it has poor discriminatory power in some cases (Bosshard et al., 2006; Mignard and Flandrois, 2006). As mentioned above, the two *B. thermosphacta* and *B. campestris* type strains share >99.3% sequence identity with regard to their 16S rRNA genes (Stackebrandt and Jones, 2006). Real-time PCR assays have been developed for detecting and quantifying *B. thermosphacta* from beef, seafood, and pork sausage (Mamlouk et al., 2012; Papadopoulou et al., 2012; Fougy et al., 2016). Some were based on primers designed from the 16S rRNA gene sequence (Mamlouk et al., 2012; Papadopoulou et al., 2012) and may not differentiate the two species. On the contrary, in a most recent report, the primers designed from the *rpoC* gene were specific for *B. thermosphacta* only (Fougy et al., 2016). Two PCR-based tests for specific detection and differentiation of *B. thermosphacta* and *B. campestris* were developed (Gribble and Brightwell, 2013). The first is a real-time TaqMan PCR based on a single nucleotide polymorphism (T/A) and targeting 16S rRNA gene sequences. This test allows the specific differentiation of *Brochothrix* species from the closely related *Listeria* and *Lactobacillus* genera. The second is a standard PCR assay for the specific identification of *B. campestris* based on the amplification of the brochocin-C encoding operon. This bacteriocin is produced by the *brcABIDT* operon (McCormick et al., 1998) which is absent from *B. thermosphacta* (Siragusa and Cutter-Nettles, 1993; Gribble and Brightwell, 2013). However, this reportedly species specific PCR test may not be reliable as the studies on brochocin-C have all been performed with the type strain, *B. campestris* ATCC 43754. Thus, there is no information about the presence of the genes for brochocin-C production in other *B. campestris* strains that could validate this PCR test as accurate on more strains.

Other DNA based methods such as PFGE (Pulsed Field Gel Electrophoresis), REP-PCR (Repetitive Extragenic Palindromic PCR) were also applied on *B. thermosphacta* strains with the aim to characterize the intra-species diversity (Xu et al., 2010; Papadopoulou et al., 2012). The results obtained by these authors confirmed a genetic diversity between the strains. MALDI-TOF MS (Matrix assisted laser desorption/ionization time of flight Mass spectrometry) based on the analysis of protein profiles enabled the identification of *B. thermosphacta* colonies isolated from poultry cuts but no indication about the possible identification of *B. campestris* with this method was mentioned (Höll et al., 2016).

The use of culture-independent methods, performed with no need of prior bacterial cultivation, has greatly improved the knowledge about the diversity and the structure of microbial communities of food. By such methods the presence of *B. thermosphacta* among the dominant species has been highlighted in many food matrixes including meat and seafood products (Drosinos and Nychas, 1996; Jaffrès et al., 2009; Pennacchia et al., 2009, 2011; Ercolini et al., 2011; Nieminen et al., 2012; Chaillou et al., 2015; Delhalle et al., 2016; Piotrowska-Cyplik et al., 2017).

Spoilage Potential of *B. thermosphacta*

Production of Malodorous Molecules

The spoilage of food can be evaluated by sensory analyses which reveal color, aspect, odor, taste with attributes (such as buttery odor or wet dog as examples) and sometimes notation. Chemical analyses can also be performed to identify and sometimes quantify the molecules that are produced and considered as responsible for spoilage. In the case of off-odor production, methods aiming at detecting volatile molecules have been largely used. As *B. thermosphacta* has been reported to be one of the most common species associated with spoilage, many studies have analyzed volatile organic compounds (VOCs) in food contaminated by this species, to establish a link with its presence or activity in spoiled products. Table 3 summarizes the different molecules that have been identified as putatively linked to the presence of *B. thermosphacta* and its involvement in spoilage of various food matrices.

Table 3 Volatile Organic Compounds produced by *B. thermosphacta* during storage of meat or seafood under air, vacuum packaging (VP) and modified atmosphere packaging (MAP)

Volatile organic compounds (VOC)	Matrix	Storage conditions	Odor description	Other spoilage bacteria	References
<i>Hydrocarbons</i>					
Dimethylbenzene	Inoculated peeled and cooked shrimp	MAP (50% CO ₂ , 30% N ₂ , 20% O ₂), 5°C, 10 days	Strong butter, buttermilk, sour, nauseous sweet	/	Laursen et al. (2006)
2-Octene	Inoculated peeled and cooked shrimp	MAP (50% CO ₂ , 30% N ₂ , 20% O ₂), 5°C, 10 days	Strong butter, buttermilk, sour, nauseous sweet	/	
<i>Alcohols</i>					
Ethanol	Inoculated beef meat	VP, 5°C, 15 days		/	Stanley et al. (1981)
	Inoculated chicken breast fillets	MAP (30% CO ₂ , 70% O ₂), 4°C, 7 days		/	Franke and Beauchamp (2017)
1-Propanol	Inoculated peeled and cooked shrimp	MAP (50% CO ₂ , 50% N ₂), 8°C, several weeks (spoiled)	Cheese/feet and sour/fermented	/	Jaffrès et al. (2011)
2-Methyl-1-propanol	Inoculated peeled and cooked shrimp	MAP (50% CO ₂ , 50% N ₂), 8°C, several weeks (spoiled)	Cheese/feet and sour/fermented	/	
2-Methyl-1-butanol	Inoculated peeled and cooked shrimp	MAP (50% CO ₂ , 50% N ₂), 8°C, several weeks (spoiled)	Cheese/feet and sour/fermented	/	
3-Methyl-1-butanol	Spoiled chicken carcasses	Air		<i>Shewanella</i> , <i>Serratia liquefaciens</i>	Nychas et al. (1998)
	Inoculated beef meat	Air, 4°C, 7 days		/	Casaburi et al. (2014)
	Inoculated chicken breast fillets	MAP (30% CO ₂ , 70% O ₂), 4°C, 7 days		/	Franke and Beauchamp (2017)
	Inoculated peeled and cooked shrimp	MAP (50% CO ₂ , 30% N ₂ , 20% O ₂), 5°C, 10 days	Wet dog	<i>Carnobacterium maltaromaticum</i> , <i>Carnobacterium divergens</i> <i>Carnobacterium mobile</i>	Laursen et al. (2006)
2-Methylpropanol	Inoculated peeled and cooked shrimp	MAP (50% CO ₂ , 50% N ₂), 8°C, several weeks (spoiled)	Cheese/feet and sour/fermented	/	Jaffrès et al. (2011)
	Spoiled chicken carcasses	Air		<i>Pseudomonas</i> spp. <i>S. liquefaciens</i> ,	Nychas et al. (1998)
2-Methylbutanol	Inoculated beef meat	VP, 5°C, 15 days		/	Stanley et al. (1981)
	Inoculated beef meat	VP, 5°C, 15 days		/	
1-Octanol	Inoculated beef meat	Air, 4°C, 7 days		/	Casaburi et al. (2014)

The spoilage effect of *B. thermosphacta* has been studied in different food matrices either from naturally contaminated products (Dainty et al., 1985, 1989; Dainty and Mackey, 1992; Ercolini et al., 2011; Nosedá et al., 2012) or in challenge test experiments performed after inoculating sterile or low contaminated food matrices (Stanley et al., 1981; Joffraud et al., 2001; Jaffrès et al., 2011; Casaburi et al., 2014; Mikš-Krajník et al., 2016; Franke and Beauchamp, 2017). As shown in Table 3, these studies reported that *B. thermosphacta* brings about spoilage by producing various undesirable VOCs comprising aldehydes, ketones, esters, alcohols, and small amounts of short chain fatty acids causing off-odors and off-flavors (Ordóñez et al., 1991; Casaburi et al., 2014, 2015). This species also produces organic acids (lactic and acetic acids) and ethanol (Hitchener et al., 1979; Pin et al., 2002).

Some of the spoilage-related molecules produced by *B. thermosphacta* may have a very intense off-odor or off-flavor, and therefore affect the sensory quality of the product even at low levels (Refsgaard et al., 1999). For example, acetic acid has an undesirable pungent, acidic, and vinegar flavor even at low concentrations (Vermeiren et al., 2005). The amounts of the spoilage related molecules may vary depending on strains and on the nature and concentration of the substrates available (glucose, glycerol, ribose, branched-chain amino acid, and fatty acids among others) (Macaskie et al., 1984; Borch and Molin, 1989; Vermeiren et al., 2005).

The apparition of creamy/dairy and buttery odors are associated with the production of high amounts of acetoin and diacetyl, respectively (Stanley et al., 1981; Dainty and Hibbard, 1983; Dainty and Mackey, 1992; Nychas et al., 2008; Casaburi et al., 2014). Both compounds are major end products of the aerobic catabolism of glucose by *B. thermosphacta* (Blickstad, 1983; Pin et al., 2002).

In relation to seafood products, *B. thermosphacta* has been reported to have an important role in the spoilage of cooked and peeled shrimps stored under MAP (Mejlholm et al., 2005; Jaffrès et al., 2011), and of fresh and VP smoked salmon filets (Mikš-Krajník et al., 2016); (Joffraud et al., 2001; Stohr et al., 2001). For example, in cold-smoked salmon *B. thermosphacta* produced mainly 2-hexanone and 2-heptanone responsible for the formation “blue-cheese” off-odor (Joffraud et al., 2001; Mejlholm et al., 2005; Laursen et al., 2006). In cooked and peeled shrimp, *B. thermosphacta* was related to the strong butter, buttermilk-like, nauseous, sour/fermented and cheese/feet off-odors associated with the production of 2,3-butanedione (diacetyl), 3-methyl-1-butanal, and 3-methyl-1-butanol (Mejlholm et al., 2005; Laursen et al., 2006; Jaffrès et al., 2011). It has been shown that factors affecting the biochemical composition of food products may determine the nature of the VOC and therefore affect the type and the intensity of spoilage (Koutsoumanis and Nychas, 1999; Skandamis and Nychas, 2002; Nychas et al., 2008). Other factors can influence spoilage by *B. thermosphacta*, as notably the presence of diverse bacterial genus and species in the food microbiota, and the possible interactions between them. Indeed, it has been reported that when co-inoculated on cooked and peeled shrimps, *B. thermosphacta* and *C. maltaromaticum* were able to form a typical wet dog off-flavor, whereas neither produced this off-flavor when inoculated separately (Laursen et al., 2006). No new metabolite was detected in *B. thermosphacta*–*C. maltaromaticum* co-cultures by comparison with those produced by both species inoculated alone. It can therefore be hypothesized that the wet dog off-flavor is most probably resulting from an interaction between metabolites formed by both species.

Obviously, a more in depth investigation is necessary to clearly understand the metabolic pathways which lead to the production of VOCs by *B. thermosphacta*.

Production of Biogenic Amines (BAs)

B. thermosphacta has been also associated with the production of biogenic amines (BAs) in some studies (Paleologos et al., 2004; Casaburi et al., 2014). These compounds, such as histamine, tyramine, tryptamine, putrescine, and cadaverine, often result from decarboxylation of free amino acids. Some BAs are responsible for strong putrid off-odors and some, as histamine, for foodborne poisoning. Histidine decarboxylase and tyrosine decarboxylase, responsible for histamine and tyramine synthesis, respectively, have been reported for several bacterial species. Although histidine decarboxylase activity has been reported in *B. thermosphacta* (Casaburi et al., 2014), no histidine decarboxylase gene was found in the genome (Stanborough et al., 2017). This may suggest that BAs production is strain dependent in *B. thermosphacta*, as already described in lactic acid bacteria (Coton and Coton, 2009). Furthermore, during co-cultures, *B. thermosphacta* has been reported to enhance the cadaverine production of *Escherichia coli* and can also promote the production of histamine by *Lactobacillus sakei* (Nowak and Czyżowska, 2011). This shows the difficulty to clearly demonstrate the spoilage activity of bacteria in food products.

Strategies for Fighting *B. thermosphacta* Food Spoilage

Biopreservation

Biopreservation has been described in 1996 by M.E. Stiles as “extended storage life and enhanced safety of foods using the natural microflora and (or) their antibacterial products” (Stiles, 1996). The addition of bacteria as protective cultures, of their metabolites like bacteriocins or other antagonistic compounds, or the use of bacteriophages having antagonistic effects reflect examples of biopreservation. The inhibition of *B. thermosphacta* using bacteriocins has primarily focused on nisin. This bacteriocin, produced by *Lactococcus lactis*, is applied as a food preservative (E234) in the food industry, particularly in some dairy products but not in meat or fish where *B. thermosphacta* commonly occurs. However, several studies focused on the addition of nisin in beef carcasses and meat products to inhibit the growth of *B. thermosphacta* (Cutter-Nettles and Siragusa, 1996a,b, 1997; Tu and Mustapha, 2002). Cutter-Nettles and Siragusa (1994) demonstrated that nisin spray treatment of beef carcasses can reduce the level of *B. thermosphacta* by up to 3.6 log CFU cm⁻² after aerobic incubation during 24 h at 4°C. The same authors showed later on that nisin spray treatment combined by VP was more effective as resulting in reducing *B. thermosphacta* by up to 4.5 log CFU cm⁻².

(Cutter-Nettles and Siragusa, 1996b). Additionally, nisin immobilized in a calcium alginate gel limited the growth *B. thermosphacta* on ground beef and beef carcasses to undetectable levels ($<1.30 \log \text{CFU g}^{-1}$) (Cutter-Nettles and Siragusa, 1996a, 1997). Other authors demonstrated that nisin and nisin combined with EDTA treatments followed by VP could increase the shelf life of fresh beef stored at 4°C up to 25 days by inhibiting *B. thermosphacta* (Tu and Mustapha, 2002).

Brochocin-C, the two peptide bacteriocin produced by *B. campestris* ATCC 43754, inhibits *B. thermosphacta* and other closely related Gram-positive species associated with food and meat such as *Listeria* spp., *Lactobacillus* spp. and *Carnobacterium* spp. (Siragusa and Cutter-Nettles, 1993; Greer and Diltz, 2006). Brochocin-C has been described as a potential food preservative since this bacteriocin was shown to be heat stable at 100°C and its activity preserved at pH ranging from 2 to 9 (McCormick et al., 1998). However *B. campestris* can also grow and cause spoilage on vacuum packed lamb making the use of this bacteriocin producing bacterium not suitable for meat biopreservation (Gribble and Brightwell, 2013).

Protective cultures active against *B. thermosphacta* in laboratory medium and also in meat and seafood products have been reported (Fall et al., 2010, 2012; Leroi et al., 2012, 2015; Olaoye et al., 2015; Hwanhlem et al., 2017). Inoculation of cooked and peeled shrimps with *Lactococcus piscium* CNCM I-4031 inhibited the growth of *B. thermosphacta* by 3–4 log CFU g⁻¹ (Fall et al., 2012) and totally stopped its growth in cooked-smoked salmon (Leroi et al., 2015). Additionally, *L. lactis* subsp. *lactis* I23, a nisin producer, and the multi-bacteriocin producer strain *Lactobacillus curvatus* CRL705 and other lactic acid bacteria prevented the growth of *B. thermosphacta* in meat (Castellano and Vignolo, 2006; Russo et al., 2006; Olaoye et al., 2015).

Bacteriophages have also been proposed for biopreservation as an alternative for extending the storage quality of refrigerated meats (García et al., 2008). Sensory analysis of pork tissue showed a better acceptability of samples inoculated with *B. thermosphacta* and a phage solution than those inoculated only with *B. thermosphacta*, which produced undesirable odors within 4 days making the product rejected by the panel (Greer and Diltz, 2002).

Organic acids, often naturally produced by microorganisms, are used in food industry as food preservatives (Theron and Lues, 2007). The effect of lactic acid on *B. thermosphacta* has been evaluated (Grau, 1980; Niemand et al., 1983; Greer and Diltz, 1995). According to Grau (1980), lactic acid is more effective for inhibiting the growth of *B. thermosphacta* under anaerobic condition. Moreover, the product characteristics influence the inhibitory effect of lactic acid on *B. thermosphacta*. For example, lactic acid causes a stronger inhibition in fat tissue than in lean tissue (Greer and Diltz, 1995).

Plant-Derived and Other Antimicrobials

Many plants and their derived essential oils are known to delay or inhibit the growth of bacteria, yeast, and molds. These compounds have been therefore investigated for their potential and applicability to preserve food (Tiware et al., 2009). Some studies have been published on the inhibitory effects of plant-derived antimicrobials on *B. thermosphacta* (Nowak et al., 2012; Casaburi et al., 2015; D'Amato et al., 2016). For example in beef stored under oxygen-enriched MAP, thyme and rosemary essential oils have been shown to prevent the growth of *B. thermosphacta*. However, the level of their bactericidal effect varied depending on the strain they were applied to Nowak et al. (2012). Thyme essential oil was also found to strongly inhibit the growth of *B. thermosphacta* in pork meat (D'Amato et al., 2016). Thus, these antimicrobial molecules could be good alternative methods for extending the shelf life of meat. However to be suitable for commercial application, the amount of essential oils to be added is determinant for the acceptance, since their strong aromas might be transmitted to food products (Chouliara et al., 2007).

Physical Treatments

The effect of physical treatments used in food processing, as heating, gamma irradiation of high hydrostatic pressure, has been evaluated. *B. thermosphacta* is heat sensitive bacterium that is destroyed by a heating at 63°C during 5 min (Stackebrandt and Jones, 2006). *B. thermosphacta* has been reported more resistant to irradiation than other meat spoilage organisms such as *Pseudomonas* (Giroux et al., 2001). Although it has been frequently isolated from irradiated meat and poultry, this species is affected by irradiation doses of 0.5 and 2.0 kGy (Stackebrandt and Jones, 2006). Various studies have shown that high hydrostatic pressure is of great interest for food industry to extend the shelf-life of solid food products as it can inactivate most micro-organisms. Inactivation of *B. thermosphacta* has been evaluated in high pressure treated ground beef (Ouattara et al., 2002), ready-to-eat meats (Hayman et al., 2004), cooked ham (Han et al., 2010), and Indian white prawn (Ginson et al., 2015). In the case ready-to-eat meat stored at 4°C, high pressure was shown to reduce *B. thermosphacta* counts to undetectable levels until 95 days after the treatment (Hayman et al., 2004). In vacuum-packed cooked ham similar results were observed with *B. thermosphacta* counts maintained at 2 log CFU g⁻¹ 90 days after the treatment (Han et al., 2010).

Genomic Characteristics of *B. thermosphacta*

To date, 12 *B. thermosphacta* and one *B. campestris* draft genome sequences are publicly available. Genome sequences of the type strains *B. thermosphacta* ATCC 11509 and *B. campestris* ATCC 43754 were sequenced by DOE Joint Genome Institute (JGI) in 2014 in the framework of the project: Genomic Encyclopedia of Bacteria and Archaea (GEBA). More recently, eleven draft genome sequences of *B. thermosphacta* strains were determined (Stanborough et al., 2017). These strains were isolated from various meat products stored aerobically or under MAP.

Table 4 summarizes the characteristics of these genomes. All are draft genome sequences. Their size is quite similar, ranging from 2.43 to 2.64 Mb with a G+C content from 36.2% to 36.4%. Genome-based analysis performed by Stanborough et al. (2017) showed a high degree of genomic sequence similarity between the *B. thermosphacta* strains. The genome analysis highlighted diverse repertoire of substrate-specific genes from the phosphotransferase system (PTS). This includes the genes for glucose, maltose, sucrose, fructose, mannose, trehalose, cellobiose, β -glucoside, mannitol, and N-acetylglucosamine transport and phosphorylation systems. Ribose, glycerol-3-phosphate, maltose/maltodextrin and inositol transporter genes were also identified. All genes required for glycolysis were present. All genes required for the pentose phosphate pathway were also found, while coding sequences (CDS) for only four of the eight enzymes of the citrate cycle (TCA cycle) were detected. This analysis revealed also the presence of genes involved in the production of malodorous compounds as acetoin and 2,3-butanediol, with the presence of genes coding for α -acetolactate synthase, acetolactate decarboxylase and an (S,S)-butanediol dehydrogenase. As it has been suggested that free fatty acid production in *B. thermosphacta* results from amino acid catabolism rather than from lipolysis (Holley, 2014). Stanborough et al. (2017) have also searched for genes involved in the degradation of the branched-chain amino acids. They found all enzymes of these pathways leading to the production by *B. thermosphacta* of the branched-chain fatty acids isovaleric, isobutyric, and 2-methylbutyric acids from the degradation of leucine, valine, and isoleucine, respectively. These fatty acids are also responsible for off-odors production on food (Casaburi et al., 2014, 2015). As mentioned above no gene for histidine decarboxylase and histamine production was detected. Stress response regulatory genes were also identified, as for example the alternative sigma factor σ^B , which most probably plays important roles in the survival and growth under high-salt conditions and adaptation to refrigeration temperatures, and in the spoilage process. This suggests that despite the high degree of genomic sequence similarity between the *B. thermosphacta* strains, the spoilage potential for each strain is most probably related to the regulation of spoilage-specific genes expression.

Despite the temporal and the geographic diversities of the strains used for genome comparison, and also the difference in term of the meat source and their packaging conditions for strain isolation, the strain panel used does not represent an exhaustive diversity of *B. thermosphacta*. Indeed, this species has been isolated from various other ecological niches including seafood products and the environment (Stackebrandt and Jones, 2006). Therefore, sequencing other strains isolated from wider origin may help to better estimate and evaluate the diversity of *B. thermosphacta*.

Conclusion

Fig. 2 summarizes the information available on the spoilage potential of this bacterium depending on the food matrix and the storage conditions. *B. thermosphacta* is gaining the interest of researchers because it is increasingly isolated from various meats and seafood. It has been even recognized as a specific spoilage microorganism of meat products. Several studies aimed at understanding its metabolism as a function of the environmental parameters. Recently, analyzing the genome content of several *B. thermosphacta* isolates identified several genes involved in the metabolic pathways related to the development of spoilage reactions already described in *B. thermosphacta*. However, most of the genes responsible for the high number of molecules involved in the spoilage caused by *B. thermosphacta* remain yet unknown (Fig. 2). The limited genetic diversity among *B. thermosphacta* genomes may result

Fig. 2 Spoilage potential of *B. thermosphacta*. VOCs and off-odors produced in meat and seafood stored under air or MAP/VP are indicated. VOCs, which biosynthetic pathways are known, are indicated in underlined.

from the narrow ecological niche (red meats) for selecting strains to be sequenced. Therefore, sequencing the genome of other strains isolated from wider sources may help to better estimate and evaluate the diversity of *B. thermosphacta*.

In order to better understand *B. thermosphacta* spoilage, there is still a need for revealing the role of specific genes that contribute significantly to food spoilage. Discovering the influence of abiotic factors like food composition and storage conditions and of biotic factor (composition of the microbiota contaminating food) should help identifying genes responsible for spoilage activity and proposing strategies for fighting *B. thermosphacta*. A link between spoilage molecules and gene expression should be established for assessing the metabolic pathways involved in food spoilage. This should enable to deduce pertinent spoilage biomarkers (genes or molecules) for developing technologies that can prevent meat and seafood spoilage by this bacterium.

Capsules and Secreted Extracellular Polysaccharides

Caitlin Sande, Samantha Wear, and Chris Whitfield, University of Guelph, Guelph, ON, Canada

CPS and EPS Structures

Capsular polysaccharides (CPSs) maintain an association with the cell surface that is retained on centrifugation and this typically involves some form of covalent linkage to the surface. This results in a protective surface layer known as the capsule, which is clearly distinguished in micrographs (Fig. 1). In contrast, secreted exopolysaccharides (EPSs) have limited association with the cell surface post-export. Nevertheless, encapsulated bacteria inevitably shed surface material during growth, so CPS and EPS distinctions can be complicated.

It is also impossible to distinguish CPS from EPS based on the glycan components alone and these encompass a large and highly diverse range of structures. A few examples relevant to this review are presented in Figs. 2 and 3. The glycans can be composed of a wide variety of sugars and non-carbohydrate substituents, with a range of glycosidic linkages, creating polymers with repeat-unit structures of varying complexity. Most of the known structures are catalogued in a searchable database (<http://csdb.glycoscience.ru/index.html>). Structural variability can occur within a single species resulting in different serotypes. For example, there are ~80 recognized CPS serotypes each in *Escherichia coli* and *Klebsiella pneumoniae* (where they are called K antigens) and ~100 in *Streptococcus pneumoniae*, although genomics data from isolate collections suggest the actual numbers for some are potentially higher. While anionic properties are most common, some of the glycans carry no net charge. In a few rare cases, some CPSs carry both positive and negative charges due to free amines and carboxylates; the polysaccharide A (PSA) CPS of *Bacteroides fragilis* provides a high-profile example of such zwitterionic polymers and their unusual biological properties are described below. The polysialic acid CPS shared by *E. coli* K1 and group B meningococci, and the glycosaminoglycan-related *E. coli* K5 CPS, are examples of CPS structures resembling mammalian glycans and they have important implications for pathogenesis. Cellulose is an important structural component in plants and is often described as the most abundant biopolymer on earth; it is also produced as an EPS by a wide range of bacteria.

Decoration of peptidoglycan with additional glycans is a recurring theme in Gram-positive bacteria. Wall teichoic acids provide the best studied examples and are attached through a phosphodiester linkage and a linker oligosaccharide to the C6 position of muramic acid residues in the peptidoglycan backbone. A similar strategy links mycolylarabinogalactan to the peptidoglycan of mycobacteria. Covalent linkage to peptidoglycan is also employed to secure CPS in streptococci and *Staphylococcus aureus*. Although the precise structural arrangement is uncertain, serotype III CPS in group B streptococci is also linked to peptidoglycan via a phosphodiester bond but the site of linkage is the C6 of GlcNAc residues, rather than muramic acid. However, this linkage mode is not universal for streptococcal capsules because CPS from pneumococcus serotype 2 (and several other serotypes) are linked instead via a glycosidic linkage to the C6 position of peptidoglycan GlcNAc residues.

Despite extensive research, the mechanism(s) by which most Gram-negative CPS are linked to the cell surface have not been elucidated. Non-covalent charge-based interactions with other components on the cell surface may be important but these do not adequately explain the stable association with the cell surface and the inability to easily remove CPS with salt washes. Where the linkage of CPS to Gram-negative cell surfaces is known, the anchor involves a glycolipid. In the most prevalent mechanism, several CPS serotypes of *E. coli* employ a conserved glycolipid composed of several β -linked 3-deoxy-D-manno-oct-2-ulosonic acid (Kdo) residues, attached to (lyso)phosphatidylglycerol (Fig. 2). These capsules are collectively called “group 2” in *E. coli* due (in part) to a conserved assembly process. Meningococcal capsules are anchored by the same glycolipid and, based on conserved biosynthetic enzymes, this strategy is also used by a variety of other pathogens including *Haemophilus influenzae* and *Campylobacter jejuni*. The involvement of a Kdo linker between the glycan and lipid moieties is reminiscent of lipopolysaccharide (LPS) structures. However, they are distinguished by the use of α -linked Kdo residues in LPS and β -linked Kdo in CPS. Human-adapted *Salmonellae* (including isolates of serovar Typhi) and some soil bacteria belonging to the Burkholderiales produce a CPS called Vi antigen, which is anchored by a different method. Vi antigen is composed of α -linked poly-N-acetylgalactosaminuronic acid modified with 3-O-acetyl residues, resembling a modified pectin. The glycolipid anchor for Vi antigen consists of an unidentified N-acetylhexosamine residue modified with 2 acyl chains (Fig. 2), although the exact structure has not been determined yet.

The relationships between LPS-linked polysaccharides (O antigens) and capsular polysaccharides are sometimes difficult to resolve. In *E. coli*, group 4 capsules (also called O antigen capsules) possess the same repeat-unit structures as LPS-linked O antigens and LPS-free CPS; serotype K40 provides an example. In contrast, assembly and attachment of high-molecular-weight group 1 CPS

Fig. 1 Electron micrograph of encapsulated *E. coli* possessing a K1 capsule. Courtesy of Dr. Elyse Roaches, University of Guelph.

in *E. coli* (such as K30) is independent of LPS, but short K30 oligosaccharides can be linked to LPS. No covalent anchoring mechanism has been identified to explain how group 1 and 4 capsules are attached to the cell surface but Kdo-containing glycolipids are certainly not involved.

Production of CPS and EPS is not mutually exclusive. As an example, the envelope stress-regulated EPS, colanic acid, is produced by many isolates of *E. coli* and *Salmonella*. *E. coli* isolates with group 2 capsules also produce colanic acid under appropriate conditions. In contrast, those with group 1 capsules do not because the CPS biosynthesis gene locus has replaced the colanic acid locus. Like group 1 CPS, short oligosaccharides of colanic acid can be linked to LPS but the polymeric form is LPS-free. The ability of bacteria to produce and secrete multiple glycans derived from different assembly pathways is highlighted by *Mycobacteria*, which possess capsules composed of long chain α -glucans and release complex glycans including arabinomannan and mannan into the surrounding environment.

Functions of CPS and EPS

In 1928, F. Griffiths published a classic study that demonstrated the dependence of pneumococci on CPS production for the ability to cause infection in mice. These experiments have been particularly influential because they also demonstrated the transfer of genetic material and the concept of natural transformation, more than a decade before DNA was identified as the molecule carrying genetic information. CPS is now known to be a pivotal virulence factor for pneumococci and for many other pathogens of humans and livestock.

The complement system plays a critical role in host innate immunity. Bacteria possess a range of cell-surface molecules that activate the complement pathway, and the presence of a highly hydrated capsule structure can prevent the interaction of surface-bound complement with receptors on phagocytic cells. This protection is potentially overcome by deposition of C3b on CPS itself, so bacteria have developed different strategies to avoid this. For example, serotype III group B streptococci produce large amounts of CPS and the presence of Neu5Ac (sialic acid) residues mediates crucial interference with regulatory proteins that activate the alternative pathway. A comparable strategy (with different regulatory targets) occurs with polysialic acid CPS produced by *E. coli* K1 and serotype B meningococci (Fig. 2).

Opsonophagocytosis of encapsulated bacteria can be achieved via the classical pathway in the presence of CPS-specific antibodies. This provides the essential foundation for several CPS-based vaccines that have had major impact in reducing the burden of infectious diseases on a global scale. Examples include successful vaccines against *H. influenzae*, meningococci,

Lipid-linked CPS

CPS with unknown "anchors"

Peptidoglycan-linked CPS

Fig. 2 Structures of examples of capsular polysaccharides. Shown are the repeating unit structures and the modes of attachment to the cell surface (where known). The carbohydrate structures are given using the symbol convention for the sugars. Fructose (green circle), galactose (yellow circle), galactosamine (yellow square), glucose (blue circle), glucuronic acid (blue diamond), mannose (green circle), rhamnose (green triangle), glucuronic acid (green triangle), N-acetylgalactosamine (yellow square), N-acetylglucosamine (yellow square), N-acetylmuramic acid (purple square), N-acetylneuraminic acid (red diamond), 2-acetamido-4-amino-2,4,6-trideoxygalactose (white square), 3-deoxy-D-manno-oct-2-ulosonic acid (yellow circle), unidentified N-acetylhexosamine (white square).

and pneumococci. The majority of polysaccharides are T cell-independent antigens and the T cell-dependent (memory) response in effective vaccines is achieved by conjugating CPS (or fragments of CPS) to appropriate carrier proteins. The challenge of serotype diversity can be addressed with multivalent vaccines that encompass prevalent clinical serotypes. For example, Prevnar-13 targets 13 serotypes of pneumococcus and achieves sales in excess of a billion dollars annually. The effectiveness of vaccines that target defined serotypes can diminish over time due to the emergence of serotypes not covered by the vaccine, requiring new formulations. As successful as these approaches have been, they cannot overcome the problem of CPS that are poorly immunogenic due to structures that mimic "self" host cell glycans. Classic examples include a variety of CPS structures resembling host glycosaminoglycans and polysialic acids. Polysialic acid CPS mimics the glycans found on neural cell adhesion molecule (N-CAM) and certain other host components and helps neuropathogens cross the blood-brain barrier, increasing their invasiveness and leading to the high morbidity and mortality associated with meningitis. A relatively recent vaccine effective against group B meningococci (e.g., Bexsero) therefore relies on targeting multiple protein epitopes, rather than CPS.

Fig. 3 Structures of examples of extracellular polysaccharides. Shown are the repeating unit structures. The carbohydrate structures are given using the symbol convention for the sugars. Fucose ▲, galactose ●, galactosamine ■, glucose ●, glucuronic acid ◆, mannose ●, rhamnose ▲, *N*-acetylglucosamine ■, *N*-acetylglucosamine ■. The modification of bacterial cellulose with phosphoethanolamine (PEtN) is a recent discovery in γ - and β -proteobacteria.

The interaction between polysaccharides and the immune system is more complicated with zwitterionic structures. These are sometimes produced by commensal bacteria, such as *B. fragilis*, a low abundance anaerobic commensal in the gut microbiota. This organism is capable of producing at least eight CPS structures but only PSA and PSB are zwitterionic and PSA has been studied in most detail. Unlike other typical glycan structures, PSA is presented in a manner resembling protein antigens, and it induces a potent T cell-dependent response. Experiments in germ-free mice revealed that PSA influences the maturation and development of the innate immune system, as well as the maintenance of its homeostasis. In addition, PSA makes critical contributions to reducing potentially harmful inflammatory responses caused by other members of the gut microbiota. Collectively, these effects provide a major benefit in human health.

Lactic acid bacteria in the intestinal microbiota are also implicated in homeostasis of innate and adaptive immunity and their EPS may also possess immunostimulatory properties. Their ability to promote proliferation of macrophages and modulate levels of pro- and anti-inflammatory cytokines has been known for some time and several studies have also suggested certain lactobacillus EPS possess the ability to suppress the proliferation of tumor cell lines. Levans have been ascribed a wide variety of properties, including provision of dietary fiber, as well as offering antiobesity, anticholesterolemic, hypolipidemic, antioxidant, and

immunostimulatory activities. The underlying mechanisms for these effects are mostly uncertain but they are presumably important elements in the probiotic capabilities of bacteria such as lactobacilli and *Bifidobacterium* species.

While the prior discussion focuses on interactions with mammalian (primarily human) hosts, CPS and EPS structures also play important roles in plant-associated bacteria. Plant symbionts, such as members of the Rhizobiaceae, produce complex branched EPSs (e.g., succinoglycan) with frequent non-sugar substituents, as well as CPS structures which bear structural and biosynthetic relationships to the group 2 capsules of *E. coli*. These glycans are essential for success of the symbiotic relationship with legumes, although their precise involvement is not fully understood. Some functional overlap seems to exist between various bacterial surface glycoconjugates in these bacteria, reflecting the complexity of host-symbiont interactions. EPS and CPS may be involved in the later stages of infection thread formation and nodule development. However, they are also implicated in suppressing the plant host defense response. In plant pathogens, EPS (such as xanthan gum in *Xanthomonas campestris*) causes wilting by blocking xylem vessels and this can lead to the production of lesions that promote invasion and survival in plant tissues.

The biofilm mode of growth is a key part of the lifestyle of many bacteria, occupying a wide range of environmental niches. In biofilm communities, bacteria are embedded in a matrix of proteins, polysaccharides and extracellular DNA. As a result, CPS and EPS contribute (directly or indirectly) to the wide range of properties ascribed to biofilms. CPS is implicated in the formation of intracellular biofilm-like communities (IBCs) in uropathogenic *E. coli* and O antigen capsules are important for gallstone biofilms formed by *Salmonella*. However, such examples are limited and in some cases CPS actually impair biofilm formation. In contrast, EPS are central architectural components in biofilms. The importance of poly-N-acetylglucosamine (PNAG) and cellulose (Fig. 3) is well documented in this context. Cellulose production is predominantly a Gram-negative trait and the capacity of cellulose to assemble into filaments, as well as higher-order structures with proteins, is an important element in its function. PNAG was initially reported as polysaccharide intercellular adhesin in *S. aureus* but is prevalent in a remarkably wide range of Gram-positive and Gram-negative bacteria. Other bacteria make EPS that share structural features (and presumably physical properties) with PNAG; PEL EPS from *Pseudomonas aeruginosa* provides a good example. Growth in biofilms is often associated with elevated intrinsic resistance to antibiotics and several studies with bacteria including *P. aeruginosa* and *Acinetobacter baumannii* have described the ability of purified EPS to bind or adsorb antibiotics. Such associations depend on the glycan structure and the antibiotic examined, so structural principles are not understood, nor is the overall importance of this process relative to the additional cellular defenses against antibiotics. Some negatively-charged EPS are known to bind metals and recent work with colanic acid in *E. coli* suggests that this may contribute to preserving transmembrane potential during envelope stress in biofilms. Finally, EPS has been implicated in the ability of several bacteria to survive dessication.

While the majority of functional studies have focused on microbial pathogenesis and host interactions, CPS also play a pivotal role in protecting against infection and possible lysis by bacteriophages. The CPS layer prevents the bacteriophage from interacting with (more conserved) receptors at the cell surface. To counter capsular layers, some bacteriophages possess highly specific glycosidases in the tail assembly that cause local CPS depolymerization and allow access to underlying receptors. The host range of these bacteriophages is typically restricted to cells bearing a particular capsule structure since engagement of the glycanase seems to be required for infection. However, possession of glycanases with multiple specificities is possible, with one recent example encoding genes for nine CPS depolymerases active against different *K. pneumoniae* CPS types. Nevertheless, resistance to bacteriophage infection may be a leading driver for the diversification of CPS structures within many species. Given the current interest in bacteriophage therapy, it is perhaps not surprising that capsule-specific bacteriophages have been used to clear model infections by encapsulated bacteria. The depolymerases themselves are considered to have potential as therapeutic agents for acute infections, since their activity removes a cellular layer which is deployed to protect the pathogen against host defenses.

Biosynthesis of CPS and EPS

The basic principles of the biosynthesis of CPS and EPS are shared with those of LPS O antigens. Both require activated sugar nucleotide precursors in the cytoplasm and end with a polymerized glycan at the external face of the cytoplasmic membrane. Three different strategies have been described for CPS/EPS biosynthesis and these are distinguished by the type of acceptor used in polymerization, the membrane topology of the polymerization step, and the process for export across the cytoplasmic membrane (Fig. 4). Post-polymerization the cell envelope of Gram-negative bacteria dictates additional complexity for surface translocation of the product. The main assembly approaches are described here but some emerging systems have features that cross the boundaries.

Wzy Polymerase-Dependent Systems

Wzy-dependent polysaccharide biosynthesis was first described in the late 1960s in O antigen-biosynthesis. This process involves undecaprenol phosphate as an acceptor and appears to be the predominant mechanism when the glycan product has a complex branched structure. Examples include the group 1 CPS of *E. coli*, most streptococcal CPS, as well as colanic acid, xanthan gum and EPS from lactobacilli (Figs. 2 and 3). Their biosynthesis pathways are characterized by generation of undecaprenyl diphosphate-linked repeat units in the cytosol. The process (Fig. 4) is initiated by a phosphoglycosyltransferase (PGT) enzyme, with the pyrophosphoryl linkage in the lipid intermediate created by transfer of a sugar-1-phosphate from a nucleotide diphosphosugar to the undecaprenol phosphate acceptor. Additional glycosyltransferases then complete the carbohydrate structure in the repeat

Fig. 4 Cartoon showing the three main assembly strategies for production of CPS and EPS from sugar nucleotide donors. The upper panel shows the typical components of membrane-embedded assembly complexes and these are discussed in detail in the text. The products of the assembly processes can follow different paths in Gram-positive and Gram-negative bacteria. The lower panel shows the typical components for glycan translocation in Gram-negative bacteria. The manner in which the translocation complexes penetrate the peptidoglycan is unknown. Generalized working models are described here but some emerging systems have features that cross the boundaries, so exceptions do exist. The unfilled shapes in the cytoplasmic membrane in the lower two panels represents the relevant biosynthesis complex for each system.

unit, which can be further modified by non-carbohydrate substituents (usually in the cytosol). This is followed by export across the cytoplasmic membrane by a Wzx protein homolog; these are membrane transport proteins belonging to the multidrug/oligosaccharidyl-lipid/polysaccharide (MOP) family. The MurJ flippase involved in peptidoglycan biosynthesis is another MOP family member. Following export, the lipid-linked repeat units serve as substrates for the strategy-defining Wzy polymerase, whose

catalytic-site is located at the periplasmic side of the membrane. The structure and mechanism of the integral membrane Wzy protein remains a key open question in this field. The polymerization reaction is regulated in an unknown manner by polysaccharide copolymerase (PCP) family 2 proteins, which possess cytosolic bacterial tyrosine (BY) kinase activity. Most Gram-negative members are PCP-2a proteins and contain transmembrane and cytosolic kinase domains in a single polypeptide, while the Gram-positive PCP-2b versions frequently separate these domains in a two-polypeptide format. The polymerization activity is dictated by cycling the phosphorylation state of C-terminal tyrosine residues, through the opposing activities of the PCP-2a/b kinase and a cognate phosphatase. Oligomers of PCP-2 proteins facilitate transphosphorylation between monomers in the complex and, in the streptococcal example, phosphorylation also coordinates capsule production with cell division.

In Gram-positive bacteria, the finished product is ligated to oligosaccharides of peptidoglycan. This reaction has clear parallels with the late steps in wall teichoic acid assembly. The phosphodiester linkages attaching teichoic acids to muramic acid residues are catalyzed by proteins belonging to the LytR-Cps2A-Psr family. The inclusion of Cps2A in this family suggests a common linkage mechanism for attachment of capsules but the actual situation is still unclear given the linkage of CPS to GlcNAc, the apparent use of phosphodiester and glycosidic bonds in different systems, and the retained CPS attachment in some *cpsA* mutants.

In Gram-negative bacteria, undecaprenyl diphosphate-linked oligosaccharides provide substrates for LPS O-antigen ligase and, after attachment of O antigen to LPS, the finished molecules then enter the LPS translocation pathway. In contrast, high-molecular-weight glycans follow a specific CPS/EPS translocation pathway composed of a tetramer of PCP-2a proteins interacting with an oligomer of outer membrane polysaccharide export (OPX) proteins. This creates a contiguous channel spanning the periplasm and outer membrane for CPS. Unlike porin proteins, which use β -strands to form channels across outer membranes, the prototype OPX protein (Wza from *E. coli*) uses amphipathic α -helices. Wza forms a stable octameric structure that contains the nascent CPS/EPS during its passage to the cell surface but details of the entry of the glycan from the polymerization center into the channel are unknown. Working models have involved comparison with tripartite drug efflux pumps in Gram-negative bacteria, with the PCP component fulfilling the role of the adapter proteins that provide an interface between the membrane pump and the outer membrane channel.

The features that distinguish CPS and EPS in this late step are also still unanswered. EPS could potentially be released by an incomplete Wzy reaction that would normally transfer the nascent glycan from its undecaprenol diphosphate carrier to the next repeat unit. However, this does explain retention of capsules, where no additional anchor molecule has yet been identified. While it is possible that the nascent glycans are never released from the final undecaprenol diphosphate carrier in the capsular form, this would limit each assembly complex to the production of a single CPS chain. Such questions offer intriguing avenues for future research.

Export of CPS Glycolipids by ABC Transporters

CPSs with defined glycolipid anchors are assembled without undecaprenol phosphate involvement. The widespread lyso(PG)-Kdo anchor from *E. coli* group 2 (and related) capsules offers the best studied example and involves the catalytic activity of two conserved CMP-Kdo-dependent β -Kdo glycosyltransferases (called KpsS and KpsC in *E. coli*). The β -Kdo oligosaccharide is then extended by addition of the CPS repeat-unit domain in a polymerization process involving sequential sugar transfer and is completed in the cytoplasm. In the *E. coli* K1 and *S. Typhi* Vi CPS, a single catalytic site is responsible for polymerizing the CPS domain. In other representatives, multiple glycosyltransferase catalytic sites are often accommodated in single “polymerase” polypeptides. The biochemical pathway for Vi antigen is less certain as the current data cannot confidently distinguish between models where the terminal diacyl *N*-acetylhexosamine residue is an acceptor, from one where its addition serves as a terminating reaction.

The details of the export of the completed CPS glycolipids via the ABC transporter are unknown but, given the size constraints imposed by the potential lumen of ABC transporters, a processive strategy is favored in working models, resembling that recently proposed for an ABC transporter that exports undecaprenyl diphosphate-linked O antigen. In this context, it is perhaps significant that most documented CPSs relying on these transporters have linear backbones, or possess single residue substituents. Structures for ABC transporters that export undecaprenyl diphosphate linked oligo- and polysaccharides for protein *N*-glycosylation and O antigen synthesis, respectively, invoke a model where the lipid is excluded from the transporter lumen and the same may be true for CPS. The transporter itself likely recognizes structural motifs in the shared lyso(PG)-Kdo glycolipid acceptors since transporters can be exchanged between systems with diverse repeat-unit structures.

Currently, for CPS assembly, ABC transporters are confined to Gram-negative bacteria and are therefore coupled to additional translocation machinery to complete the transfer to the cell surface. This consists of a PCP-3 protein and an OPX representative. PCP-3 proteins form multimers but lack BY-kinase domains. Genetic data supports PCP3 recognition of cognate OPX proteins but the OPX proteins are unable to form stable complexes, and their structural features have yet to be described. As with the Wzy-dependent pathways, comparisons have been made with tripartite drug efflux pumps in Gram-negative bacteria, but recent studies concerning Vi antigen export indicate some exposure of periplasmic intermediates, rather than a protected translocation pathway from the cytosol to the outside of the cell. The glycolipids on the CPS chain termini provide a means to attach the nascent product to the cell surface and create a capsule, and this may explain why ABC transporters have not been implicated, to date, in EPS export.

Synthase-Dependent Mechanisms for EPS Production

Bacterial cellulose and poly-*N*-acetylglucosamine (PNAG) are examples of EPSs secreted by a wide variety of bacteria. The characteristic biosynthetic feature of these systems is that polymerization occurs without the involvement of a lipid acceptor, and

synthesis and export across the cytoplasmic membrane are catalyzed by the same protein(s). Cellulose synthase provides the best example from the perspective of biochemical and structural insight, with two proteins (BcsA and BcsB) forming the active complex. BcsA is an integral membrane protein with a cytosolic processive glycosyltransferase. Most of BcsB is located in the periplasm but it also contributes a transmembrane helix to the integral membrane structure formed primarily by BcsA. BcsA and BcsB are both required for synthesis and they create a channel leading from the active site of the glycosyltransferase domain across the cytoplasmic membrane, so synthesis and export are obligatorily coupled. This two-protein architectural principle seems to be conserved in other EPS-producing synthases, as is the possession of a PilZ regulatory domain to facilitate regulation of the synthase by cyclic di-GMP. Binding of the effector to the PilZ domain in BcsA results in a conformational change that allows access of the UDP-glucose substrate into the catalytic site. In some members of the α - and β -proteobacter (including *E. coli* and *Salmonella*), additional enzymes modify the cellulose backbone with phosphoethanolamine (PEEN).

In Gram-negative bacteria, translocation of synthase products to the cell surface requires a β -barrel outer membrane channel. It is thought that a multiprotein complex spans the periplasm linking the channel and the synthase. A periplasmic scaffold is contributed by a protein containing an extended region composed of tetra-tricopeptide repeats (TPR). TPR motifs are protein interaction domains and synthase-dependent EPS production machinery often possess associated periplasmic enzymes that depolymerize or modify the glycan product. In PNAG, for example partial de-*N*-acetylation can have a significant effect on PNAG rheological properties. Such modifications can influence the assembly and export processes.

Levansucrases

The systems described above build glycans or their repeat units in the cytoplasm. Several Gram-negative and Gram-positive bacteria produce polysaccharides called levans from sucrose-based substrates, using fructosyltransferase or levansucrase enzymes that are attached to the outer cell surface or secreted into the growth medium. These enzymes can produce both oligo- and polysaccharides, catalyzing different reactions depending on the nature of the acceptor: hydrolysis using water as the acceptor, transfructosylation of monosaccharides-oligosaccharides, or polymerization of levan EPS using growing fructan chains.

Inhibition of CPS and EPS Biosynthesis

Given the important functions of CPS and EPS in pathogenic bacteria, there is significant interest in identifying inhibitory compounds that block production and potentially render the bacterium susceptible to host defenses. The similarities in folds and mechanisms shared by glycosyltransferases and sugar nucleotide synthases used to generate glycans in both host and pathogen create some challenges in these approaches, as does the wide range of activities for the repertoire of glycan structures. However, there are sufficient novel elements that are shared within a given assembly-export strategy to offer some avenues. Small molecule inhibitors targeting regulatory proteins and outer membrane channels for CPS translocation have been reported. In addition, some attempts to eradicate biofilm-forming bacteria have focused on interfering with the synthesis and signaling mediated by cyclic di-GMP, which would have a direct impact on the function of key synthase enzymes. However, a very promising different strategy for eradicating biofilms has been developed by using glycosylhydrolases that depolymerize the EPS within the biofilm. In an unusual twist, some of the effective candidate matrix-degrading enzymes tested to date actually originate from the periplasmic modification machinery involved in EPS production.

Biotechnological Applications

Since their varied structures confer distinct physical properties, CPS and EPS have received considerable commercial attention. Bacterial cellulose is produced in large quantities by organisms like *Komagataeibacter* (formerly *Acetobacter*) *xylinum*, where microfibrils intertwine to create impressive sheets or “pellicles” at the air-liquid interface of broth cultures. The genes required for modification of cellulose with PEEN residues are absent in the larger (commercial) producers such as *K. xylinum*. Bacterial cellulose has a smaller filament diameter and higher purity than cellulose sourced from plants, making it the preferred material in pharmaceutical applications such as wound dressings, artificial skin, and tissue grafts. The product can be also impregnated with a variety of compounds to promote tissue regeneration or prevent infection.

The gelling properties of EPS have been exploited in a range of applications. Xanthan gum has a large market presence but products belonging to the sphinghan family of EPSs (Fig. 3) also have potential. Xanthan is frequently found as a food additive where a stable colloidal emulsion is required. It can be produced in optimized fermentation conditions in yields approaching 30 g/L and forms high molecular weight chains (exceeding 10^6 Da), and is an excellent thickener, even at low concentrations. This EPS possesses unusual and valuable rheological properties, where its viscosity is reduced at high temperature or low ionic strength, which offers advantages in handling and application. As a result, it has seen a variety of other applications as a stabilizer in other commercial settings, including as cosmetics, textiles and oil recovery. Xanthan has also been used (alone or combined with other polymers) in tablets and hydrogels for drug release or as supports for cell proliferation approaches. *Lactobacillus* EPSs provide another important additive in the food industry because these bacteria are generally regarded as safe and are found in a variety of

fermented dairy and vegetable products. The EPS, and its interactions with other components, contributes to the texture of the product. However, unlike an additive like xanthan, the EPS is produced *in situ*.

In a different biomedical application, polysialic acid is of interest for improving the effectiveness of therapeutic proteins and drugs. The objective is to enhance the (often) short half-lives of therapeutics in circulation after administration. Chemical modification with polyethylene glycol (PEG) is often used in this role, to reduce susceptibility to proteolysis, antibody response and clearance that hampers therapeutic protein efficacy. However, PEGylation has some drawbacks and modification with polysialic acid offers an alternative strategy, where the lack of immunogenicity of polysialic acid presents a significant advantage.

There is considerable interest in glycoengineering strategies that seek to use the enzymes from biosynthesis pathways (CPS, EPS and others) to create tailored glycan structures or entirely new glycoconjugates for biomedical and industrial purposes. This is already founded in natural glycan diversity, where lateral gene transfer and recombination within a biosynthesis gene locus leads to structural and antigenic diversification. This same principle can be used in targeted fashion, where glycosyltransferases with different specificities can be used to create new backbone or side-chain structures. This approach is limited by the acceptor specificities of known enzymes and must preserve processes that initiate on a required lipid carrier, as well as structural motifs that are essential for export and surface presentation. The efficiency of the combinatorial system is paramount, since yield determines commercial potential. However, one area where glycoengineering has been already seen success is the production of neoglycoconjugate vaccines using the protein glycosylation machinery. Periplasmic O- and N-glycosylation transfers oligosaccharides and polysaccharides to a protein. This provides an alternative to the chemical conjugation approach and allows precise determination of the site and frequency of glycosylation of a carrier protein of choice. The mechanism of the oligosaccharyltransferase requires the glycan be assembled on undecaprenol phosphate and the periplasmic location creates a need for export of the glycosylation donor to the periplasm. The power and flexibility of this strategy is evident in its successful application in the generation of glycoconjugates bearing LPS O antigens and CPS from pneumococci and *S. aureus*, which possess Wzy-dependent assembly mechanisms.

Glossary

Chemotaxis Motility directed by a sensory/motor system along a gradient of a solute.

Cytoskeleton Protoplasmic proteins that participate in the development and/or maintenance of cell shape.

Oligotrophy Of the habitat: Condition of the habitat characterized by low organic productivity and low density of microbial populations. Of microbes: Nutritional class of microbes whose competitiveness in their natural habitat depends on their ability to exploit a scarcity of nutrients.

Periplasm Region immediately external to the cell membrane; in Gram-negative bacteria, the region is separated from the environment by a second superficial, outer membrane.

Phosphorelay Systematic transfer of phosphoryl groups from a nucleotide triphosphate through a series of proteins, thereby altering the functional activity of each protein; important in many signal-transduction systems.

Prostheca An outgrowth of the Gram-negative bacterial cell surface that includes the outer membrane, the cell membrane, and the peptidoglycan layer; may or may not include cytoplasmic elements.

Sacculus The rigid peptidoglycan layer of a bacterial cell envelope; in Gram-negative bacteria, the sacculus lies within the periplasm.

Stalked sibling The product of asymmetric fission in *caulobacter* that bears a prostheca and is not motile.

Swarm sibling The product of asymmetric fission in *caulobacter* that bears a flagellum and is motile.

TonB-dependent receptors Periplasmic proteins that assist in providing metabolic energy for active transport of solutes across the outer membrane of a Gram-negative bacterium into its periplasm.

Transcription cascade System of sequential transcription of genes within which transcription of each 'later' gene requires activation by the product of an 'early' gene.

Abbreviation

GS/GOGAT Glutamine synthetase/glutamate-oxoglutarate amino transferase

Defining Statement

Caulobacters are aquatic, oligotrophic bacteria with a distinctive reproductive cycle that produces flagellated swarmer and non-motile stalked cells as siblings. Correlations between their oligotrophy and their asymmetrical division are drawn against the background of description of the molecular details of development now available from extensive research with *Caulobacter crescentus*.

Caulobacter and Caulobacters

Prologue: It was not a dark and stormy night; it was an overcast day, and the sky was a smooth gray. Nevertheless, the water of the lake was blue; it was unquestionably clean and oligotrophic. A caulobacteriologist scooped samples from the lake's surface with great expectations. Within 2 weeks, the collector was rewarded by finding that 75% of the 3177 aerobic, chemoorganoheterotrophic bacteria per milliliter that formed visible colonies on a dilute peptone medium were caulobacters.

Recognizing Caulobacters

The Genus *Caulobacter*

Species assigned to the genus *Caulobacter* are aquatic, oligotrophic, aerobic, freshwater, Gram-negative Alphaproteobacteria. All the distinguishing morphologic features of the genus *Caulobacter* are evident in the dividing cell (see Figs. 1–4):

[☆]*Change History*: June 2017. Emanuele G. Biondi replaced Figs. 9 and 10; modified section "Control of Development: Protein Synthesis, Modification, Localization, and Destruction"; and updated "References" and text throughout the article.

This article is an update of J.S. Poindexter, *Caulobacter*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 57–73.

- An elongated, unicellular form – straight (rods or fusiform cells), curved (curved rods or subvibrios), or twisted (vibrios) – with poles that are blunt (rods) or tapered (vibrios, subvibrios, and fusiform cells);
- A different appendage at each pole: a single flagellum at the younger pole, and at the older pole a prostheca composed of the cell envelope (outer membrane, peptidoglycan layer, and inner membrane);
- A discrete blob of adhesive material, the ‘holdfast’, at two sites: at the flagellated pole at the base of the flagellum, and at the outer tip of the prostheca (hence its designation as a cellular ‘stalk’);
- A constriction at approximately the midcell that, when completed, will separate a flagellated ‘swarmer’ cell from its nonmotile stalked sibling;

Fig. 2 Bacteroid cells of *Caulobacter* sp. strain CB417 grown in dilute peptone yeast extract medium. EM, negatively stained with AmMoO₄. Marker=1 μm.

Fig. 3 Fusiform cells of *Caulobacter leidyi* strain CB37 grown in dilute peptone yeast extract medium. See also Fig. 8(b). EM, Pt-shadowed. Marker=1 μ m.

Fig. 4 Biprosthate cells of *Asticcacaulis biprosthateum* strain C-19 grown in dilute peptone yeast extract medium. EM, Pt-shadowed. Marker=1 μ m.

- Ringed disks of peptidoglycan and proteins, called stalk bands, at intervals along and within the stalk; one band is installed during each cell cycle and records the number of fissions completed by the cell since it began to develop its stalk. The rings look very much like the flagellar base plates first described in spirilla.

Other Caulobacters

Variations on this morphology are exhibited by closely related Alphaproteobacteria. The closest relative is the genus *Asticcacaulis* (literally, nonadhesive stalk). Although not adhesive, *Asticcacaulis* stalks are banded. The genus is distinguished from caulobacter by several morphologic features.

- Cells of all isolates are blunt rods.
- Locations of the holdfast, flagellum, and prostheca are not coincidental; the holdfast is located excentrically on the pole, the flagellum excentrically at the same pole, and the prostheca may be excentral, subpolar, or lateral. Isolates with lateral prosthecae may bear one or two prosthecae, although only one flagellum.
- Fission occurs by septation rather than constriction.
- A difference in size of the siblings, with the swarmer regularly much shorter than its stalked sibling during and immediately after fission, and a greater difference in cell cycle times between the siblings (see Fig. 9).

Both *Caulobacter* and *Asticcacaulis* fall into the 16S rRNA family 'Caulobacteraceae', as do *Brevundimonas* (a composite taxon of phenotypically diverse bacteria) and *Phenylobacterium* (a genus of non-prosthecae bacteria). Some of the species currently assigned

to *Brevundimonas* were originally named as *Caulobacter* species because they possess all the ecologic, morphologic, and physiologic features described for that genus.

Two other 16S rRNA families of the class *Alphaproteobacteria* include genera with caulobacterial morphologies. One species (*C. leidyi*) is placed in the family *Sphingomonadaceae* on the basis of its lipid content as well as its 16S rRNA. Isolates similar to *C. leidyi* are known, but not yet named or classified. The family *Rhodobacteraceae* includes the marine caulobacters of the genus *Maricaulis*. Dividing cells of these alpha-proteobacteria are identical to *C. crescentus* in microscopical appearance of their dividing cells, and their stalks are adhesive; however, stalk bands are typically absent.

The Caulobacterial Stalk

The term 'prostheca' was introduced by J.T. Staley to designate an outgrowth of the bacterial cell surface that includes at least the peptidoglycan sacculus (Fig. 5); this definition distinguishes prosthecae from proteinaceous structures such as flagella and pili/fimbriae, and from extracellular polysaccharidic capsules and slime stalks. Known prosthecae bacteria are Gram negative, but not all are Alphaproteobacteria. Among dimorphic prosthecae bacteria that produce swarmer cells, the features of the dividing cell described above for caulobacters are – as far as known – unique to the three families of Alphaproteobacteria already mentioned. The caulobacterial prostheca lacks cytoplasm and DNA. It does not generate progeny, a reproductive process that occurs in the dimorphic bacteria of the genera *Hyphomicrobium* and *Hyphomonas*, where the nonadhesive prostheca produces swarmers by budding from its distal tip.

The value of motility in an aquatic organism is never debated. Adhesion, likewise, is generally regarded as adaptive because it can anchor the organism in a favorable locale. Although adhesion of a bacterium typically does not require a prostheca, adhering bacteria are very often perpendicular to the substratum. While this allows most of the cell surface to continue in contact with the liquid phase of the aquatic environment, an adhesive prostheca increases that advantage by preventing crowding of the cell body against other bacteria attached to the same substratum.

Only among the caulobacters is the prostheca typically adhesive, and adhesiveness is not a universal property even within this group. It is therefore an unavoidable challenge to infer possible functions for the stalk other than a role in adhesion. To date, three further functions have been proposed: (1) increased resistance to settling in an aquatic environment ('buoyancy'); (2) increase of the nutrient uptake-mediating area of the cell surface; and (3) boosting the incipient swarmer above the crowd to free it from entrapment in a biofilm. (1) The difference in buoyancy of non-stalked and stalked siblings is the mechanical basis for segregation of swarmers from their stalked siblings by differential centrifugation, which is the most widely used method for the establishment of synchronously developing populations used in cell cycle research with caulobacters (see Section 'Bacterial Filaments'). (2) Besides straightforward geometric reasoning, there is biochemical, physiological, developmental, and molecular (genetic and proteomic) evidence that supports the proposed role of the stalk in nutrient scavenging. Even stalks severed from the cell body mechanically or as a consequence of genetic mutation are demonstrably capable of accumulating solutes, and to consume metabolic energy doing so. (3) Observations of caulobacters attached to natural materials reveal only dispersed and not crowded caulobacters; swarmers tend to be well away from their stalked siblings before settling down. However, on both animate and inanimate surfaces exposed to

Fig. 5 Peptidoglycan sacculi of caulobacters. EM, positively stained with uranyl and rotary shadowed with Pt. Marker=1 μ m. (a) *Caulobacter crescentus* strain CB2. (b) *Asticacaulis biprosthecum* strain C-19. Marker=1 μ m.

caulobacter populations at 1000-fold or greater than their usual density in natural waters, and in the absence of predators such as protozoa and microfauna, caulobacters can be forced into crowds – a technique that can be useful in technological applications that employ immobilized caulobacters.

Accordingly, the caulobacter stalk is demonstrably capable of providing at least four functions. It mediates adhesion in a fashion that simultaneously exposes most of the cell surface to the liquid surroundings, the source of the cell's nutrients and lifts the cell body above a biofilm, promoting free dispersal of the motile sibling. Because the stalk engages in little biosynthetic activity except at the cell-stalk junction (see Section 'Placement of Cytoskeletal Proteins and Cell Wall Synthesis Complexes'), it could serve (like microvilli in a mammalian intestine) to increase the ratio of nutrient-absorptive surface to nutrient-consuming protoplasm. Finally, it provides the capacity for the third ecologic habitat available in an aquatic environment: floating, as well as swimming in the water column and settling on submerged surfaces. Stalked caulobacters not attached to submerged surfaces accumulate in the neuston, or air–water interface, the shallow vertical zone in an aquatic habitat where organic substances accumulate because they diffuse less freely there than in the water column; where O_2 enters from the atmosphere; and where the local phototrophs, the primary producers, tend to gather during the day and catch the sun's energy that will support the local chemo-heterotrophs such as caulobacters. Thus, bacteria with this peculiar morphology and developmental cycle are well suited to living competitively in low-nutrient-flux aquatic environments as aerobic, metabolically efficient, nutrient-scavenging chemo-organo-heterotrophs. As mentioned in the Prologue, it is precisely where they are most dependably found as the predominant (but not crowded) aerobic, non-photosynthetic bacteria.

Capture and Cultivation of Caulobacters

The natural environment in which caulobacters thrive and can sometimes even predominate is low-nutrient-flux water, both fresh and marine. Even when predominant, caulobacters do not accumulate as dense populations; they are rarely as crowded as 10^5 – 10^6 cells per milliliter. Natural waters are almost never constant in nutrient flux; even the most oligotrophic water will experience transient surges of nutrients that will support a responding increase in the density of the microbial populations and of the organisms that feed on the microbes. During such periods, caulobacters do not necessarily disappear, but they do not respond by multiplying rapidly. Consequently, they can be overwhelmed numerically by faster-growing bacteria such as pseudomonads and become difficult to detect – microscopically or by cultivation.

The most dependable way to encourage caulobacters to accumulate in a culture and to enable their isolation as colonies on solidified media is to depend on their development as a dimorphic population. Let the water sample stand in a tall bottle (such as a milk dilution bottle) at room temperature in the dark. In 4–14 days, a thin, delicate surface film of caulobacters will accumulate as the swimmers rise toward the air–water interface and then develop their 'water wings' – their stalks. Their accumulation can be accelerated by adding peptone to no more 0.01% (w/v); higher concentrations will encourage the multiplication of bacteria that can grow faster, but are less capable of scavenging nutrients from low concentrations. Similarly, incubation in the dark reduces primary production by phototrophs in the sample. Their activities interfere with the enrichment of caulobacters in two ways: by producing and exuding organic compounds, often amino acids, thereby enriching the water; and by serving as attachment surfaces for the caulobacters and reducing their buoyancy. The stalked bacteria probably do quite well attached to phototrophs, but they are harder to find because they sink out of the surface film.

A sample of surface film can be examined in a wet mount to determine whether the relative abundance of stalked cells is increasing, and when it is, a sample can be streaked on an unbuffered medium containing 0.05% peptone and not more than 1% agar, and incubated at room temperature. As colonies begin to appear, it is instructive to mark those that are macroscopic by the third day of incubation; in the author's experience, such colonies are never generated by caulobacters from enrichment samples. After 1–2 weeks, new colonies no longer appear and the preparation for screening can begin.

There is a fast, frustrating way to screen, and a tedious, fruitful way. The fast way is to examine samples of colonies in wet mounts. Because the medium is dilute, the colonies are very small (rarely more than 0.5–0.8 mm), and a colony (especially if cohesive) is easily consumed in the preparation of the mount; consequently, finding them is not capturing them. The tedious way is to patch a sample of each colony onto a gridded plate of medium, incubate for about 2 days, and then prepare wet mounts from the growth in the patches. This actually saves considerable time because the patches can be sampled in a pattern and marked off if they contain caulobacters, whereas using primary colonies requires that the colonies be mapped. Better yet, the patch is not consumed in the preparation of a wet mount.

Water can be surveyed for the presence of caulobacters by molecular tools such as FISH probing. There are, however, practical problems with fluorescence microscopical techniques. For example, natural populations of caulobacters are sparse, whether they are predominant or vastly outnumbered by non-caulobacters. It is often more difficult to detect them as fluorescent dots than as bacteria that wave about on their stalks in a focal plane above other bacteria settled on the slide. Their motion reveals their presence and their stalks identify them. Fluorescence intensity of a probe-binding caulobacter cell may be low and difficult to discern, for more than one reason: (1) Caulobacter cells in wild samples are relatively small, often not much wider than 0.5 μm , binding too little probe to be discerned readily; (2) Ribosomal content is often very low in cells from oligotrophic conditions, and relatively little probe is bound; (3) Most of the 'universal' probes used in community surveys are intended to bind to 16S rRNA. However, the caulobacters most frequently encountered in freshwater are members of the rRNA family *Caulobacteraceae*, the only family in the order *Caulobacterales*, which is a fairly discrete and congruous taxon as currently defined. Again, reaction with a fluorescent probe

may be weak, and even competent application of probes can fail to detect a caulobacter signal in a sample that will yield a dozen or more different kinds of isolates – from which more can be inferred than just natural distribution.

To identify the colonies or patches containing stalked bacteria, the wet mount should be examined with phase-contrast illumination; the hydrated stalk is about $0.2\ \mu\text{m}$ in diameter, just at the limit of resolution of a good phase-contrast microscope. If only ordinary light is available, preparing the mount in a droplet of dilute methylene blue will provide some contrast and help reveal some stalks. When crowded (as when growing on an agar surface), caulobacters adhere to each other in rosettes (see Figs. 6 and 7), and as their stalks elongate they will appear in one or another arrangement. In *Caulobacter*-like organisms, the stalks will be oriented like the spokes of a wheel, with the cell bodies sticking outward toward the rim of the wheel or like pins in a pincushion (Fig. 6). In *Asticcacaulis*-like organisms, the cells will appear to be in contact with each other at the poles, with the nonadhesive prosthecae extending from the cell cluster. *Asticcacaulis biprosthecum* rosettes (Fig. 7) are especially distinctive as 'hairy' rosettes. The remainder of the procedure is a routine bacteriological restreaking until only one type of colony can be found on plates streaked from successive colony samples.

Colonies of caulobacters may be translucent or opaque. They occur in various shades of yellow/gold/orange/red-orange due to cell-associated carotenoid pigments; pale pink due to an unidentified non-heme, non-carotenoid pigment; or colorless (unpigmented). As they age, colorless colonies often become dark tan-pink or pink-red due to heme accumulation. The colony margins are entire, the outline is circular, and the elevation is convex. Texture may be soft and watery, butyrous, compact and slightly sticky, or very cohesive and smooth or granular. Under each strain's optimal conditions of cultivation, colonies of most isolates become visible macroscopically between 60 h and 4 days of incubation – 3–4 days being most common. In liquid culture, doubling times of

recent isolates range from 2.5 to 5–6 h, which is somewhat faster than they seem to manage in nature. As determined by the rate of accumulation of bands in the stalks of caulobacters captured by their adhesion to EM grids submerged in a mesotrophic lake, the reproductive rate in situ in early summer is three generations per day or 8 h per generation.

Faster-growing clones with doubling times close to only 2 h have been generated by laboratory cultivation from at least two species (*C. crescentus* and *C. leidy*). These two species are the only caulobacters that can be grown in chemically defined media; vitamins (riboflavin, biotin, or cyanocobalamin) are required by some isolates, but are not sufficient for growth without complex supplementation with low concentrations of peptone, casamino acids, or yeast extract. Amino acids – commonly exuded by algae – are generally their preferred sources of both carbon and nitrogen; besides amino acids, many organic acids and several sugars can be consumed as carbon sources. Cellobiose, the disaccharide produced by the digestion of cellulose, is used by almost all isolates in the author's collection; this might explain in part the frequent occurrence of cytophagias in successful caulobacter enrichments.

Morphogenesis and Oligotrophy

It has long been suspected that one of the most important functions of the stalk is to increase the capacity of the caulobacter cell to scavenge nutrients from the oligotrophic environments where caulobacters are competitive. Very early in the studies with pure cultures of caulobacters, it was discovered that the nutrient with the most dramatic influence on morphogenesis of the stalk was phosphate: phosphate inhibits stalk elongation, and phosphate limitation results in a marked acceleration of stalk outgrowth (see Fig. 8 and Section 'Phosphate and Stalk Elongation'). These observations were a stimulus to the notion that stalk development improves specific nutrient scavenging by the caulobacter cell, at least for phosphate. The inhibitory effect of phosphate can be mitigated by calcium, and the accelerating effect of phosphate scarcity requires available calcium. Although an abundance of the molecular details of development has been elucidated in *C. crescentus*, the interaction of phosphate and calcium in stalk elongation is yet to be explained in comparable detail. Nevertheless, in the natural habitat of caulobacters, phosphate and calcium are not typically available in excess together because of the insolubility of calcium phosphate; in caulobacters, calcium could serve as an indicator of phosphate scarcity.

Nitrogen-source availability has little demonstrable effect on stalk elongation, but starvation or limitation for nitrogen has a marked effect on stalk initiation (see Section 'Nitrogen Source and Stalk Initiation'). In nitrogen-adequate media in the laboratory, the swarmer cell sheds its flagellum and begins its maturation (initiating stalk development and DNA synthesis) after a motile stage that lasts about 25–33% of the cell cycle time. In nitrogen-inadequate media, the transition from motile, juvenile swarmer to non-motile, reproductively capable stalked cell is postponed indefinitely and may not occur until nitrogen becomes available. The only nutrient-specific chemotactic response so far demonstrated in *C. crescentus* by the Adler capillary assay is the attraction of nitrogen-limited swimmers toward nitrogen sources (ammonium and amino acids); in contrast, even swimmers produced under nutrient-limited conditions (whether for carbon or nitrogen or phosphorus) do not clearly respond to carbon sources or phosphate. Thus, two types of observation reveal that nitrogen limitation is the only nutritional signal that results in perpetuation of motility, in specific chemotaxis, and in delay of maturation of the swarmer into the reproductive stage. This phenomenon depends on glutamine deprivation triggering ppGpp production, which in turn extends the swarmer stage. Together, these observations imply that the motility of the swarmer stage serves within the cell cycle to lead the cell toward a nitrogen-adequate site.

Fig. 8 Cell and stalk elongation in phosphate-exhausted cultures of caulobacters. EM, Pt-shadowed. Marker = 1 μ m. (a) *C. crescentus* strain CB2; See also Fig. 1. (b) *C. leidy* strain CB37; see also Fig. 3.

Caulobacters generally prefer amino acids as their nitrogen source, but they can consume inorganic nitrogen. However, *C. crescentus*, at least, lacks glutamic dehydrogenase and depends on the high-affinity GS/GOGAT (glutamine synthetase/glutamate-oxoglutarate amino transferase) pathway for the assimilation of ammonium. As in enteric bacteria, the activity of the *C. crescentus* system is inhibited and its synthesis is repressed by ammonium. As a consequence, *C. crescentus* growth is ammonium sensitive in minimal media, and the bacteria can starve for nitrogen in the midst of abundance when ammonium is the only nitrogen source available. In laboratory cultures, relief of that interference is achieved by the supplementation of defined media with glutamate to enable ammonium assimilation via GS/GOGAT or by the substitution of nitrate for ammonium.

Limitation for any one of the three macronutrients carbon, nitrogen, and phosphorus dramatically increases the uptake rate and affinity specifically for the limiting nutrient. Again, as in the case of stalk hypertrophy, phosphate limitation has the most striking effect: the relative increase in uptake rate (calculated as per unit area of cell surface) is about 80-fold for phosphate, but only about eightfold for carbon or nitrogen sources. Uptake of non-limiting nutrients does not change with the stalk length. The long-stalked cells of phosphate-limited populations take up phosphate rapidly and with high affinity through both the cell body and the stalk, and their swarmer siblings exhibit a comparable enhancement of phosphate uptake. Nevertheless, while the stalk surface seems no more active in nutrient uptake than the rest of the cell, it lacks cytoplasmic components such as ribosomes and DNA. Thus, the hypertrophied stalk should provide the cell with an extension of the supply route for nutrients without increasing the nutrient demand by the most expensive metabolic activity, which is protein synthesis, or by the demand for phosphorus by nucleic acid synthesis.

A further aspect of caulobacterial nutrient-scavenging capacity was revealed in the fully sequenced genome of *C. crescentus*. There are in that genome loci that are interpreted as genes for TonB-dependent receptors, which are components of the systems for transducing metabolic energy to the outer membrane of Gram-negative bacteria that enables active uptake of solutes into the periplasm. Enteric bacteria have a few (not more than ten) such genes, and there are 34 in the highly versatile and competitive bacterium *Pseudomonas aeruginosa*. *C. crescentus* possesses 65. At least 19 such receptors appear in the proteome of isolated stalks, providing the strongest molecular evidence that the stalk is capable of energized, high-affinity uptake of solutes. Translocation to the cell body cytoplasm of solutes taken into the periplasm of the stalk probably involves periplasmic ATP-binding proteins, but the mechanism of translocation is still hypothetical.

In the oligotrophic waters that are the natural habitat of caulobacters, primary production of organic carbon is typically limited by the availability of phosphate or – less often – of nitrogen compounds, particularly nitrate. The dimorphy of caulobacters presents itself as a composite of adaptations that fits their ecologic role as nutrient scavengers, with the motile stage sensing nitrogen adequacy for stalk development and stalk elongation proceeding as needed for phosphate acquisition. The remaining major nutrient is organic carbon, which they presumably take up and transport into the cytoplasm with their exceptional battery of high-affinity TonB-dependent receptors. Those systems may enable caulobacters to collect the by-products of photosynthetic CO₂ fixation as those substances are released by the phototrophs to which caulobacters so commonly adhere and with whom they must compete for phosphorus and nitrogen.

Nutrient gradient-directed motility, extension of nutrient uptake surface relative to cytoplasm, nutrient uptake assisted by high-affinity TonB-receptor systems, and adhesion to phototrophic microbes all combine to make typical caulobacters highly competent for oligotrophy. Their unique reproductive cycle, which produces one offspring that will move away from its immobile sibling, also largely ensures that siblings will not crowd each other and therefore will not compete for sparse nutrients. Some of the details of the mechanisms that confer on caulobacters' unique approach to the problem of resource acquisition are described in the next section.

Development in *Caulobacter crescentus*

In 1935, on the basis of microscopical observations of mixed, wild (uncultivated) populations of caulobacters, Henrici and Johnson correctly inferred that a swarmer cell would develop a stalk and then proceed to asymmetric fission of a cell with a flagellum at one pole and a stalk at the opposite pole. They observed that such fission generated two siblings: a flagellated swarmer cell and a non-motile sibling bearing a stalk. However, because they lacked pure cultures, they could not determine whether a swarmer cell could divide without first attaching to a substratum and/or developing a stalk. This double question was answered in the first extensive studies with pure cultures of a variety of caulobacters, during which it was found that mechanical segregation of non-stalked (swarmer) cells from stalked cells allowed separate cultivation of each cell type. Early studies with such populations revealed that newborn swarmer cell populations were synchronous with respect to flagellum shedding, stalk development, and completion of fission, and that fission was invariably preceded by the other two events. Synchrony in a stalked cell population was less stringent; nevertheless, a full round of cell division was completed in about 75% of the time required for a full round of cell division in a population that began as swarmers.

Continuous direct observation of mixed populations in microcultures revealed behavior that was entirely consistent with the behavior of the synchronous cultures: the cell cycle was significantly shorter for a cell that entered the cycle with its stalk than for a cell that was observed from its motile stage, and the latter type of cell became non-motile and began to develop a stalk before it elongated, constricted, and divided. Fission of non-stalked cells was not detected. The absence of any difference in sequence or timing of morphogenetic and cell cycle events in populations attached to glass cover slips or suspended in agitated liquid cultures implied that adhesion was not required as a signal for flagellum shedding or the initiation of stalk outgrowth.

Within a few years after these initial studies, one species, *C. crescentus*, attracted the attention of microbial cell biologists who began to explore its dimorphic cell cycle. In the hands and minds of these diligent scientists, *C. crescentus* has proved a fertile experimental system that has yielded details of the mechanisms that enable a unicellular bacterium to order and integrate its morphogenesis, reproduction, and physiologic properties. The studies have also established that this 'simple' organism is a complex cell in which functional compartments can be established by the localization of proteins, without the elaboration of intracellular barrier membranes so familiar in eukaryotic cells.

Although there are some variations (rigidly enforced within a species), the cyclical sequence of developmental events in the lives of all caulobacter cells is largely a story of poles. The entire tale can be perceived at every *C. crescentus* pole from the birth of the pole as a product of fission to its maturation as an adhesive, banded stalk. It begins with the formation of the pole when fission is completed in generation I (see Fig. 9). During generation II, begun by that fission, the sequence of developmental events at each new pole will be the same, but the time course of those events will depend on the age of the opposite pole; developmental events will occur sooner at the new pole of the sibling with a stalk at its older pole (in the 'stalked sequence' in Fig. 9) than at the flagellated cell's new pole (in the 'swarmer sequence' in Fig. 9). Maturation of each pole formed in generation I will occur in generation III. In short, the pole's story has three chapters:

1. The pole is formed by cell fission.
2. Extrusion events occur that confer motility, adhesiveness, and phage reception.
3. The flagellum and motility and phage receptors are lost and the pole elongates as a stalk.

The long version of this story is now remarkably detailed as the result of research that has employed mutations, inhibitors (particularly, inhibitors of cell wall synthesis), genomic and proteomic analyzes, physiological studies, environmental manipulations, and studies of cellular composition and protein localizations. The research has yielded an elaborate description of the development of cell shape and of functional appendages in a unicellular bacterium whose unique morphology and cell cycle have been creatively exploited as a model system for the elucidation of bacterial cell biology (For the reader interested in full-length versions, several reviews are listed in the Further Reading section).

Fig. 9 Sequence of pole development events in several successive generations. The sequences are displayed here in parallel to emphasize that the sequences are identical at the sibling poles (green is the stalked pole, while orange is the swarmer pole) formed by any one division process. However, the swarmer sequence in the second generation is typically about 1.33 times as long as the sequence occurring in its stalked sibling.

Division and the Development of Cell Shape

Cell Wall Synthesis

The shape of a bacterial cell requires maintenance by a rigid element, which is a sacculus (see Fig. 5) of peptidoglycan, sometimes called 'murein'. The best-known pathway of synthesis in a Gram-negative bacterium occurs at three locations in a Gram-negative bacterial cell:

1. In the cytosol: small-molecule precursors are synthesized by intermediary metabolism, then combined into precursors of the repeating unit of the cell wall polymer.
2. At and within the cell membrane: the saccharide pentapeptide is delivered to the inner, cytoplasmic surface of the cell membrane, transferred to a lipid carrier, and moved into the membrane, where a second saccharide unit is added to the lipid-carried precursor. This disaccharide-pentapeptide-lipid carrier is then conveyed through the membrane to its outer periplasmic surface.
3. On the outer surface of the cell membrane and in the periplasm: the disaccharide pentapeptide is transferred from the lipid carrier to an acceptor site (either an end recently synthesized or a position opened by a lytic enzyme) on the preexisting peptidoglycan of the sacculus in the periplasm. This process elongates the glycan backbone of the peptidoglycan as the lipid carrier is recycled within the membrane. Transpeptidases then strengthen the sacculus by crosslinking between the outer D-alanine pair of one pentapeptide and the free amino group on the diamino amino acid (most commonly diamino pimelic acid) of another glycan chain.

The details of synthesis vary among bacteria; nevertheless, the overall process is general for Eubacteria, and similar systems occur in some Archaea.

Peptidoglycan synthesis complexes can affect the shape of an elongated cell when they are active at three regions:

1. Along the length of the cell to support elongation along the cell's long axis. So far as known at present, the complexes are arranged as a helix in rods, vibrios, spirilla, and fusiform cells.
2. At midcell to provide new peptidoglycan for constriction or septation. So far as known at present, the complexes are arranged as a ring in this location.
3. At a cell pole to support polar outgrowth such as occurs in budding and/or prosthecate bacteria. A specific geometric pattern of installation has not yet been discerned.

Research on bacterial cell shape development is, in large measure, research on peptidoglycan synthesis, and is aided by the availability of natural and artificial products that specifically inhibit one or another synthetic step. Example of inhibitors used in studies of *C. crescentus* morphogenesis include cycloserine, which inhibits the formation of D-alanine-D-alanine from L-alanine in the cytoplasm; vancomycin, which inhibits trans-glycosylation at the outer surface of the cell membrane; and β -lactam compounds such as amdinocillin that inhibit crosslinking in the periplasm. Van-FL, a derivative of the cell wall synthesis inhibitor vancomycin, binds to and detects the D-alanine-D-alanine moiety of uncross-linked peptidoglycan. It can be used to tag nascent peptidoglycan in bacteria with highly crosslinked peptidoglycan, particularly Gram-positive species. However, the peptidoglycan of *C. crescentus* is not highly crosslinked, and Van-FL tagging probably does not adequately distinguish sites of particularly active peptidoglycan synthesis from less active or even inactive sites.

Bacterial Filaments

Three bacterial proteins homologous to cytoskeletal proteins of eukaryotic cells appear to guide the placement of cell wall synthetic complexes in *C. crescentus*:

1. FtsZ, a GTPase, is a tubulin homolog that participates somehow in cytokinesis (pole formation); in *C. crescentus*, it also participates in stalk initiation (pole outgrowth).
2. MreB is an actin homolog whose principal role appears to be to guide cell elongation.
3. Crescentin may be homologous to intermediate filaments of animal cells; it accumulates within the cytoplasm on the concave side of vibrioid cells and appears to generate cell curvature and possibly also twisting. Discovered in *C. crescentus*, its role in bacteria other than caulobacters has not yet been established, but similar proteins are anticipated.

The properties and functions of these cytoskeletal proteins have been investigated in rods such as *Escherichia coli* and *Bacillus subtilis*, and in staphylococci, and the research with *C. crescentus* has been particularly fruitful in elucidating the dynamic nature of their localization during the course of a cell cycle. In such research, *C. crescentus* cells offer two marked advantages over other bacteria: the relative age of each cell's two poles can be inferred in microscopical preparations, and one synchronous developmental sequence can be followed by the procedurally simple means of differential centrifugation that segregates the non-stalked cells (swarmers) from their distinctly more buoyant stalked siblings.

Placement of Cytoskeletal Proteins and Cell Wall Synthesis Complexes

In *C. crescentus*, microscopical studies have revealed a hierarchy of proteins' subcellular localizations in which the accumulation of one protein at a site facilitates or is necessary to the subsequent accumulation of other proteins.

These studies have employed a molecular biological toolkit of chemicals, mutants, and highly specific genetic manipulations, the details of which are beyond the scope of this article. They have enabled investigators to follow events in deletion mutants that cannot produce specific proteins, in strains that overproduce specific proteins, and others that can be depleted (by inducible promoters or temperature) of specific proteins due to the cessation of synthesis or when a specific protein accumulation is dispersed by being depolymerized. Sequence, duration, and location of specific events are followed by the fluorescence of fusion proteins or by protein-specific fluorescent antibodies. The studies have depended heavily on observations of the events in the swarmer sequence (see Fig. 9), where synchrony is far tighter than in populations of stalked cells.

In *C. crescentus*, as in most bacteria so far examined, FtsZ is present at the site of constriction during cytokinesis. Associated with this ring are peptidoglycan-synthesizing complexes that contain MurG, the trans-glycosylase that adds the second sugar to the monosaccharide-pentapeptide-lipid carrier. The completed precursor is then flipped from the cytoplasmic to the periplasmic surface of the cell membrane, an activity currently attributed to RodA, an integral cell membrane protein. As constriction is completed, FtsZ is visible within each incipient pole. When the siblings separate, the polar FtsZ disappears due to proteolytic destruction that seems faster in the stalked than in the swarmer sibling.

As the swarmer sequence progresses, FtsZ synthesis resumes when the flagellum is shed and DNA replication begins (see Section 'The Core Regulatory Cascade of Transcription Regulation'). The new FtsZ appears first as an ensemble of short arches that extend the entire length of the cell within the cytoplasm. It is accompanied by MreB, also able to form arches, and by a third arch-forming protein, MreC, in the periplasm. A fourth protein (this is not a full list) known to become part of this system is PBP2, a periplasmic transpeptidase. As the complexes mature, peptidoglycan synthesis can occur along these arches, and the cell elongates.

Early during DNA replication, the three membrane-associated proteins FtsZ, MurG, and MreB (at least) are directed to begin accumulation as a ring at midcell. As this region matures, the synthesis of peptidoglycan causes elongation from midcell toward the poles. At about the same time, a third site of synthesis is established at the older pole and initiates elongation of that pole as a stalk. The proteins apparently responsible for stalk elongation, which occurs only at the cell-stalk junction, include MreB and RodA. After the midpoint of DNA replication, constriction becomes apparent as the midcell site of peptidoglycan synthesis develops into two new poles. Meanwhile, because the swarmer's sibling lacked a motility period during which DNA synthesis and peptidoglycan synthesis at the pole were suspended, these events have already occurred in the stalked-cell sibling. In both siblings, cell wall synthesis at the cell-stalk junction appears to pause during cell separation, then resume, probably as soon as DNA synthesis resumes in the next cycle.

Two mechanisms could explain how a protein recognizes and positions itself at a particular location. Its structure could confer on it an affinity for another macromolecule, the target; such molecular recognition is one of the most important properties of proteins. Alternatively, it could encounter a barrier at some sites that prevents its close approach or binding; by default, it would then bind only at barrier-free sites. Both mechanisms are reasonable and already described; both beg the question of what places the target or the barrier. So far, in *C. crescentus* studies of these peptidoglycan-shaping proteins, only FtsZ seems capable of finding its own way within the cell relatively independent of the other pole- and surface-localizing proteins involved in shaping the cell. Nevertheless, others in this set of proteins (particularly MreB) are required to lead the cell wall synthetic complexes to the FtsZ. In some bacteria, FtsZ rings can form only in areas within the protoplast that do not contain proteins that inhibit polymerization of FtsZ by stimulating its GTPase activity. These proteins also tend to be DNA-binding proteins that associate with specific genome regions so that their location is determined by the location, position, and state of replication of the DNA. Such proteins so far identified in *C. crescentus* include MipZ and ParB, which may provide a direct molecular connection between cell shape development during the cell cycle (most importantly, in this instance, constriction) and the DNA replication cycle.

What happens to a cell in which these events are deranged by chemical abuse, genetic modification, or malnutrition? Cell shape becomes bizarre – lemons rather than vibrios; abnormally wide stalks; stubby or branched or multiple or misplaced (ectopic) stalks; filamentous cells that divide infrequently; and so on. Specific aberrations help investigators interpret the function of a missing participant in shape determination or protein placement, as does recovery toward normal shape following relief of an inhibitory condition. Without or before relief, many cells disintegrate and die.

Extrusion Events at the Younger Cell Pole

'Extrusion' is used here to refer to the assembly of cell components, other than the typical outer membrane of a Gram-negative bacterium, that are located superficially, external to the cell membrane, and installed only at cell poles (except, of course, in *Asticcacaulis*; see Section 'Other Caulobacters'). Freshwater caulobacters such as *C. crescentus* also produce and assemble a surface array, or S-layer, on the exterior of the outer membrane. However, that layer is made constantly through the cell cycle, covers the entire cell body and stalk surface evenly, and consists of a single major exported protein. Although it is presumably of great value to the cell and has been exploited in technological applications of *C. crescentus*, it is not described here because its production, assembly, and possibly its function are neither unique to caulobacters nor an aspect of the asymmetry of development in this bacterium.

Motility: Flagellum and Chemotaxis Proteins

Assembly and activation of a flagellum at the younger pole of a dividing cell can be observed as the appendage, its activity, or its component proteins. Preparation for the development of a new flagellum begins in the swarmer cycle as the swarmer's original

flagellum is shed, motility ceases, and stalk outgrowth and DNA replication begin. Within the cell, a transcription cascade of three sets of genes begins. The products of some of these genes regulate expression of other genes in the cascade, while others' products are functional components of the flagellum apparatus. The first set ('class II genes') produce the motor switch and its ring; the second set ('class III') produce the basal body and hook; and the third set ('class IV genes') produce the flagellin subunits that are assembled into the rigid external helical filament whose rotation will propel the cell through its liquid environment. In the cascade, transcription of each successive class is required for the expression of the next class, and each set of proteins is assembled onto products of the previous set.

During the swarmer cycle, this regulatory system results in temporal (because of transcription dependence) and spatial (because of assembly dependence) ordering of the development of the next flagellum. Meanwhile, protein components needed for chemotactic sensors and response regulators are produced and accumulated in the incipient swarmer progeny as the cell begins to divide. The flagellum begins to rotate as constriction progresses at midcell, and the newborn swarmer is freely motile immediately upon separation from its stalked sibling. Within the constriction site, two proteins, TipN and TipF, accumulate that seem to mark each of the new poles as sites of flagellum assembly in the next cell cycle.

The final step in the life of a flagellum occurs in the next swarmer cycle at about the time that DNA replication begins: release of the flagellum from the older cell pole. This process is accompanied by proteolytic destruction of the motor switch protein FlhF by a specific protease, ClpXP. While the mechanism of release is not yet certain, the appearance of the shed flagella that accumulate like litter in the liquid phase of laboratory cultures is consistent with a cleavage-effected separation. The filament, the hook, and the rod are still an intact unit, but the other membrane-associated components are absent.

Thus, the overall organization of the development of flagellar structure and function follow mechanistic principles similar to those of sacculus development, although regulation of transcription may play a somewhat larger role here. An immediate role for cytoskeletal proteins has not been demonstrated for flagellar morphogenesis, but it is clear that the positioning of the flagellar apparatus derives from the ultimate guidance of the constriction site placement by the cytoskeleton.

Adhesiveness: Holdfast and Pili

Many kinds of bacteria – aquatic, terrestrial, plant and animal associates – adhere to bulky (bulkier than bacterial cells) substrata by means of some type of adhesive substance, most commonly composed of or containing a significant amount of polysaccharide. For mechanical and/or electrostatic reasons, initiation of adhesion is often facilitated by motility of the bacterium. In many bacteria, it is also aided by sticky protein filaments (pili or fimbriae) that extend from the cell surface and enlarge the effective diameter of the cell, increasing its frequency of contact with other particles.

The younger pole of a *C. crescentus* cell is provided with all three devices for establishing persistent, stable adhesion to substrata. At about the same time that the new flagellum becomes visible and active on a dividing cell, extrusion of adhesive material (the 'holdfast') occurs at the same pole. The glue is composed of poly-N-acetylglucosamine and other components. It is the strongest adhesive known among biotic glues, stronger than the adhesives of marine mollusks. It works under water and allows caulobacters to adhere to a wide diversity of organic and inorganic inanimate materials and to other microorganisms, most commonly algae and cyanobacteria in natural samples, without damaging the substrate cells. Once sessile, a *C. crescentus* cell remains fixed in place; there seems to be no mechanism for the cell to reverse adhesion, and the holdfast seems to retain its adhesiveness indefinitely.

In several species of caulobacters, pili are also extruded by assembly at the same pole as the flagellum and holdfast, but unlike those structures, pili are not universal among isolates. In *C. crescentus*, the pili accompany the other polar structures in position and in time during the cell cycle.

Caulobacters are fun to watch. Prior to sibling separation, if the stalked pole is not attached to the slide or cover slip, the single flagellum drives the dividing cell stalk foremost. The flagellated pole can attach without causing cessation of flagellar rotation, swinging its stalked sib around with the stalk waving in the liquid in a direction that reveals that, most of the time, flagellar rotation is counterclockwise. When the siblings separate with neither of them attached to a substratum, the swarmer pauses briefly and then resumes swimming at a speed noticeably greater than it achieved while it carried the additional mass of its stalked sibling.

One seemingly awkward aspect of adhesion initiated by the swarmer is direction: the flagellum drives the cell predominantly with the adhesive, flagellated pole as posterior and the newborn, non-adhesive pole in the lead. While this should prevent adhesion to most of the particles the cell approaches, motility should assist adhesion only when the cell backs up.

In most caulobacters, the three structures important to adhesion arise at the site on the younger pole of the dividing cell that will grow outward as the stalk. In the closely related genus *Asticcacaulis*, stalk outgrowth occurs at a separate site, in one species not even at the pole (see Section 'Other Caulobacters' and Figs. 4 and 7). As the flagellum is shed and stalk outgrowth begins, the pili are retracted by depolymerization within the periplasm, but the holdfast remains on the tip of the growing stalk. In contrast to stalk outgrowth, which probably pauses during cytokinesis and certainly continues (or resumes) in each cell cycle, synthesis and extrusion of the holdfast, pili, and flagellum occur only once in the life of a pole. If the cell does not adhere to a substratum while motile, it is much less likely to do so after it sheds its flagellum and begins to develop a stalk, even though the holdfast persists. It can migrate to a new locale only through its swarmer progeny. Given such a long-term commitment to a substratum, is there any mechanism that promotes or guides adhesion of the cell to a favorable environmental site?

The answer presumably lies in the ability of the cell to move to a favorable location chemotactically. Like other motile bacteria, caulobacters are provided with a chemical gradient sensory system that influences the activity of the flagellar motor. Unlike peritrichously flagellated bacteria, these mono-flagellate swarmers do not tumble, but they do occasionally stall. Brownian motion

is sufficient to reorient the cell during a stall, and this passive tumbling results in a redirection of the cell's swimming when rotation resumes. The components of the chemotaxis system, synthesized before midcell constriction occurs, are placed at the cell poles. However, even before constriction is completed, they are swiftly destroyed by proteolysis at the stalked pole and so are inherited almost exclusively by the swarmer sibling. Proteolysis eventually eliminates the system in the swarmer sibling as it begins the transition from swarmer to stalked cell, in concert with the shedding of the flagellum.

In the limited studies of specific stimuli of chemotaxis in caulobacters, the strongest influences on this response have proved to be potential nitrogen sources. This is consistent with the striking effect of nitrogen limitation as an inhibitor of the events that begin the maturation of a swarmer into a stalked cell. It implies that a major purpose of motility in these oligotrophic bacteria is to reposition the young swarmer not only away from its sibling and into an aerated region, but toward a substratum fixed in a nitrogen-adequate location.

Bacteriophage Receptors

There is a final set of functions that are transiently present at the younger pole of a dividing cell: reception of bacteriophage. With few exceptions, the attachment of bacteriophage produced by caulobacters is pole-specific, and the pole is the same for all such viruses – the flagellated, sticky pole. All the RNA phages of caulobacters attach to the pili; at least one type of DNA phage attaches to the flagellum; and the majority of DNA phages attach directly to the pole, either to unidentified components of the outer membrane or to protein(s) situated at the site through which pili are extruded. None is known to be holdfast-specific. The unusual consequence of this pole specificity is that bacteriophage infection is a 'childhood' disease of caulobacters, in the sense that susceptibility to infection depends on traits of the juvenile stage, the swarmer. As a consequence, virus infection spreads through a caulobacter population only when the environmental conditions are suitable for completion of at least one reproductive cycle – and for the production of virions.

Influence of Macronutrient Availability on Stalk Initiation and Elongation

Almost all of the nutritional experiments have been conducted with the species *C. crescentus*, which is amenable to the studies of nutritional influences because it can grow in chemically defined media. Nevertheless, one principle regarding development in caulobacters is observable with every isolate tested: development responds significantly to changes in nutrient concentration, even in complex media. Phosphate and nitrogen-source effects were recognized early; effects of carbon source, calcium, and magnesium are also known, but have received relatively little attention to date.

Nitrogen Source and Stalk Initiation

In general, caulobacter-like isolates can be cultivated in complex media containing peptones, which provide nitrogen as amino acids and peptides. *C. crescentus*, *C. leidyi*, and some *Asticcacaulis* isolates can be cultivated in media that provide inorganic nitrogen as ammonium or nitrate salts. However, because *C. crescentus* lacks the low-affinity ammonium uptake system of glutamate dehydrogenase and depends on the high-affinity GS/GOGAT system for ammonium assimilation, it starves for nitrogen when ammonium is in excess. Such starvation is relieved by supplementation of the medium with glutamate or by substitution of nitrate for ammonium. Nitrogen limitation has one long-known, demonstrable effect on the cell cycle: nitrogen unavailability causes cell cycle arrest that postpones release of the flagellum, onset of DNA replication, and initiation of stalk outgrowth. This swarmer stage arrest is linked to ppGpp production and it depends on SpoT activity.

Phosphate and Stalk Elongation

In considering stalk length in caulobacters, the age of the stalk, which grows during each cell cycle, needs to be accommodated. First-generation stalks have had only one growth period, third-generation stalks have had three growth periods, and so on. To compare two differently manipulated populations with each other with respect to stalk length, results will be informative only if stalk length is measured only for the stalks in the same generation. The first generation is by far the most variable, probably due to composite influences on two stages of stalk development – stalk initiation and stalk elongation. After the first stalk band has been installed, stalk outgrowth occurs by stalk elongation only, and that process can be evaluated separately from stalk initiation.

Phosphate concentration in finite cultures and phosphate flux in perpetual cultures (chemostats) exert striking effects on stalk development. At high phosphate concentrations or fluxes, stalk length by the end of the second cell cycle does not significantly exceed average length of siblings at the time of completion of cell constriction. During phosphate exhaustion in a phosphate-limited finite culture and most of the time in a phosphate-limited chemostat culture, second-generation stalks (with one or two bands) are several times longer than newborn cells. It is readily inferred that abundant phosphate retards stalk elongation. It probably also inhibits stalk initiation, at least in mutants that appear 'stalkless' until grown in low-phosphate conditions. Stalk initiation is, however, difficult to recognize until it is followed by stalk elongation, and so cannot be studied independently of elongation.

Like many other bacteria, *C. crescentus* possesses a Pho regulon of genes whose expression is governed by the availability of phosphate. Most of these genes occur in an operon containing at least three genes for high-affinity phosphate transport proteins and

at least three for sensing and responding to the availability of phosphate; another transport gene, *pstS*, is at a separate locus. If these genes work together in a manner similar to such genes in *E. coli* (which seems probable), the relationship between phosphate abundance and rate of stalk elongation would be as follows.

1. The proteins PstC, PstA, PstB, and PstS form a cell membrane complex capable of high-affinity phosphate transport. The complex is associated with the peripheral cytoplasmic protein PhoU, and through PhoU with the integral membrane protein PhoR. PhoU is a sensor protein and PhoR is a response modulator. The response regulator, PhoB, is cytoplasmic, not membrane-associated.

2. When phosphate is abundant, PhoR remains with the complex, but when phosphate is scarce, it is transported via the Pst complex. The passage of phosphate through the complex releases PhoR from the complex, but not from the cell membrane. PhoR then autophosphorylates (see Fig. 10(c)) and transfers its phosphate group to PhoB.

3. PhoB-P activates genes of the Pho regulon, increasing the abundance of the Pst proteins and providing other features for dealing with phosphate limitation, such as synthesis of phosphatases that enable the cell to consume phosphorus from organic phosphate compounds. In *C. crescentus*, these events are accompanied by a marked acceleration of stalk elongation.

Studies with cell wall synthesis inhibitors indicate that some of the immediate effectors of stalk outgrowth (initiation and elongation) catalyze peptidoglycan synthesis and/or modification, but no such enzyme has yet been identified as unique to stalk sacculus development. Studies of mutants that seem able to divide without stalk outgrowth when cultivated in phosphate-rich media have consistently been found able to initiate at least some outgrowth when subjected to phosphate limitation. Decades of searching for *C. crescentus* mutants that are viable yet lack at least one piece of genetic information essential to stalk development has not yet yielded such a mutant. Every *C. crescentus* laboratory has recognized the implication that because genetic stalklessness appears to be lethal, it is reasonable to regard stalk development as a process of cell surface morphogenesis that is common to pole outgrowth and pole formation. The latter process cannot be lost without eliminating division. Nevertheless, it is not unreasonable to expect that some step late in the hierarchy of regulation of stalk development could be eliminated without preventing fission, and a viable unconditionally stalkless mutant may yet be found.

Proteomic characterization of the *C. crescentus* stalk has identified several proteins that are known to participate in nutrient acquisition – for example, TonB-dependent receptors, certain outer membrane pore/channel proteins, and phosphatases and other hydrolytic enzymes that assist in increasing the transportability of charged substrates. Altogether, the stalk proteins so far identified appear to be a subset of the cell body periplasmic and outer membrane proteins; none appears to be unique to the stalk. Whether any of the stalk proteins are installed in the stalk only during phosphate limitation has not yet been systematically explored.

Control of Development: Protein Synthesis, Modification, Localization, and Destruction

The Core Regulatory Cascade of Transcription Regulation

For the first three decades or so of developmental research in *C. crescentus*, attention focused intensely on determining the cause of the postponement of developmental events in the swarmer sibling – events that occur in the stalked sibling in the same order and at the same rate, but suspended during motility in the swarmer sibling. By the early 1990s, a lengthy description of regulation through transcription control, protein phosphorylation that alter protein activities, and installation of specific proteins at specific cellular locations had been elucidated. Advances since then in genome manipulation, sequencing, and interpretation, as well as in subcellular microscopy of living cells and in physicochemical analysis of protein structure, have greatly accelerated the elucidation of further details. The core of the cell cycle's direction as described by about 1990 has proved adequate as new information has been fit into that core. Following is a brief description of the major regulatory features that govern development in both siblings: swarmer and stalked cell.

Fig. 10 Example phosphorelays (p -relays) known to influence pole development and progress through the cell cycle in *C. crescentus*. (a) CckA-initiated, ChpT-mediated, to the gene activator CtrA-P and CpdR (CpdR-P is unable to activate CtrA proteolysis). (b) ShkA-initiated, ShpA-mediated, to the gene activator TacA. (c) PhoR-initiated under conditions of phosphate limitation, to the gene activator PhoB-P.

Four regulatory proteins constitute the core of the transcriptional regulatory mechanism: CcrM, DnaA, GcrA, and CtrA. The last three of them are transcription regulators that interact with each other's genes and *ccrM*; as a group, they also control hundreds of genes whose products mediate the cell changes and assist in regulation. Most of the principles of cell cycle regulation in *C. crescentus* can be laid out in terms of these four proteins – their regulated expression, their placement relative to the cell poles, and their cyclical destruction by proteolysis.

Description of a cycle can begin at any point; the point used here is the epigenetic step: methylation of specific nucleotides close to a gene's promoter that affects the gene's transcription. Each of the other regulatory proteins activates or inhibits transcription.

1. CcrM is the DNA methylase: its methylation of DNA inhibits expression of *ctrA* and of its own gene, *ccrM*.
2. DnaA activates *gcrA*: through a multitude of other genes in its regulon, DnaA is essential for initiation of DNA replication.
3. GcrA (modulated by CcrM methylation) activates *ctrA* transcription from the first of *ctrA*'s two promoters, P1 and P2.
4. CtrA is phosphorylated by the CckA-ChpT P-relay (see Fig. 10(a)). CtrA-P has multiple regulatory effects as it accumulates:
 - a. Activation of *ctrA* through its second strong promoter, P2, providing positive feedback regulation of its own transcription;
 - b. Inhibition of *ctrA* transcription through P1, providing negative feedback of control of its transcription by GcrA;
 - c. Inhibition of transcription of *gcrA*; a, b, and c together shift responsibility for regulation of *ctrA* from GcrA to CtrA-P;
 - d. Prevention of initiation of DNA synthesis by binding near the origin of replication (*ori*), blocking the binding of the replication proteins. Initiation of DNA replication happens only once in each cell cycle in *C. crescentus*, necessarily occurring before CtrA-P accumulates;
 - e. Activation of *ccrM*, reinitiating this regulatory cascade by activating DNA replication by inhibiting transcription of *ctrA*.

The operation of this cascade results in the sequential transcription of the four genes in order: *dnaA*, *gcrA*, *ctrA*, *ccrM*. Each of the gene products DnaA, GcrA, and CcrM is effective as an unmodified protein and begins to function as it accumulates, although GcrA is further modulated by CcrM methylation of promoters. CtrA, in contrast, must be converted into CtrA-P by phosphorylation, which is the role of a phosphorelay (*p*-relay) initiated by an auto-phosphorylating kinase, CckA. CckA itself has kinase and phosphatase activity being modulated by *c*-di-GMP and stress conditions, both triggering the dephosphorylation of CtrA and CpdR.

Roles of Phosphorelays

Protein phosphorylation is a mechanism for controlling the activity of catalytic proteins, which may be activated or inactivated by the addition of one or more phosphate groups to target sites, typically serine, threonine, or histidine residues. Cells also possess phosphatases that remove the phosphate groups and reverse the direction of control. P-relays provide control of metabolism by making the phosphate groups available to the families of proteins whose activation-inactivation depends on the presence and activity of the relay components; the relays thereby serve as a buffer to balance activation among pathways and their branches and so to direct metabolic traffic. Operation of a P-relay requires, at a minimum, a kinase that transfers the phosphate group ($\sim P$) from a nucleotide triphosphate to a protein (including itself, if capable of autophosphorylation), and a phosphotransferase to move the $\sim P$ to at least one other protein. In a P-relay involved in regulation of transcription rather than of enzyme activities, one of the proteins along the relay is converted from an inactive form into a gene-activating protein that will target promoters that contain a unique, shared sequence. Activation of a set of such genes (a regulon) provides the cell with new, usually related properties simultaneously.

The genome of *C. crescentus* contains 106 genes – an exceptionally high number – for two-component signal-transduction proteins that function via P-relays. The activity of one-third of these genes rises and falls as the cell progresses through the cell cycle, implying that they participate in the regulation or they are under the control of developmental processes in *C. crescentus*. Such roles are known for two of the three examples of *C. crescentus* P-relays illustrated in Fig. 10. The CckA-ChpT P-relay (Fig. 10(a)) passes phosphate groups from ATP to ChpT, a branch point protein in the relay from which the $\sim P$ can be passed to more than one other protein. One of those proteins is CtrA; another is CpdR. The CckA-initiated relay is, therefore, integral to the core of cell cycle regulation in *C. crescentus*.

The second relay illustrated (Fig. 10(b)) transfers $\sim P$ from ATP through ShkA (the kinase) to ShpA (the phosphotransferase) and then to TacA (the response regulator). TacA-P is an enhancer-binding protein that can also be phosphorylated through CtrA-P. One of the genes activated by TacA-P, *staR*, coding an essential transcription factor for stalk elongation in nutrient-rich medium; the requirement for StaR may account in part for the known need for intact TacA for that process. The third, two-component system (Fig. 10(c)) illustrates the role of a P-relay in the response of Gram-negative bacteria, presumably including caulobacters, to environmental limitation for phosphate as a nutrient, which was discussed above (see Section 'Phosphate and Stalk Elongation').

Chromosome and Protein Localization

In the dividing cell, one copy of the origin of replication (*ori*) of the *C. crescentus* chromosome is situated at each pole. Completion of constriction separates the siblings, each with a copy of *ori* at its now-older pole. In the next cycle, as soon as replication begins (sooner, in the stalked sibling; later, in the swarmer cycle), one copy of *ori* migrates to the younger pole. Thus, for most of the cell cycle, begun either by a swarmer or by a stalked cell, the two copies of *ori* are at opposite poles.

Also prior to the completion of cell fission, the protein CpdR has somehow guided the installation of the protease ClpXP at the stalked pole. Several other proteins become localized to the poles late in the cell cycle. Motility-associated proteins of the entire

flagellar structure and chemotaxis system (e.g., McpA) are found only in the swarmer sibling, some installed in the cell envelope, others dispersed in the cytoplasm. Proteins associated with constriction (including FtsZ, MurG, and RodA; see 'Placement of cytoskeletal proteins and cell wall synthesis complexes') have gathered at about midcell. By the time the cell divides into two morphologically distinguishable siblings, they are also distinguishable by the presence of and arrangement of internal proteins. Probably most significantly, the core regulatory protein CtrA remains at ori within the stalked pole, but disperses into the cytoplasm in the swarmer sibling.

Starting Over: Proteolysis

Following the separation of the two copies of the origin of replication (ori), CtrA-P accumulates and blocks initiation of another round of replication during the remainder of the cell cycle, in both siblings. However, during constriction, while newly synthesized CtrA remains dispersed in the swarmer compartment, CtrA becomes localized at the stalked pole in the other compartment. Also localized at the stalked, but not the flagellated, pole is a complex of proteins that includes the protease ClpXP. Within that complex, ClpXP destroys the local CtrA and frees ori for the initiation of DNA replication.

ClpXP is positioned at the stalked pole of the dividing cell and does not diffuse into the incipient swarmer. Adding to the asymmetry of the next events is a role of the CckA-initiated P-relay, which is a phosphatase mode in the stalked sibling. As phosphorylation of CtrA fails, the protein becomes more susceptible to proteolysis and is destroyed, allowing DnaA to initiate DNA replication.

CtrA-P persists for a while in the newborn swarmer, but proteolysis of CtrA will occur in the swarmer sibling later – after the period of motility – and involves proteins and events that are not yet as certain as those identified in the stalked sibling. There are roles for the CckA-ChpT P-relay, a phosphatase (PleC) localized in the swarmer cytoplasm, DivK/DivK-P, and once again for ClpXP. In addition to the effects of CtrA-P noted above, CtrA-P activates *divK*, whose product inhibits the P-relay from CckA-ChpT to CpdR. Inhibition of CtrA proteolysis, an effect of CpdR-P, probably declines, allowing CtrA proteolysis in the newly-differentiated stalked cell, finally resetting the core regulatory cascade. This seems to coincide with the release of the flagellum, retraction of the pili (if present), initiation of DNA synthesis, and the onset of stalk outgrowth.

Besides CtrA, ClpXP also attacks TacA (see above), FliF, the flagellar motor switch, and McpA, a chemotaxis protein, both located at the flagellated pole. Proteolysis of FliF is a candidate as a crucial step in the release of the flagellum, which occurs close in time to the onset of DNA replication. The McpA will be replaced by renewed synthesis as the transcription cascade of flagellar genes begins again later in the cell cycle.

In summary, although the story of development in this dimorphic bacterium is a 3-chapter tale of poles, the cast of participants includes scores of proteins. The plot involves regulation of transcription; covalent modification of proteins that alters their activities; and localization of cytoskeleton-like proteins, cell wall synthesis complexes, DNA-binding proteins, and structural proteins to target sites or away from barriers. Unraveling the plot has revealed that these bacteria achieve functional compartmentalization of the protoplast by localization of proteins rather than by the familiar elaboration of internal membrane barriers seen in eukaryotic cells. Ultimately, degradation of certain participants resets the sequence and renews the cycle of events. The greater the detail in which this story is related, the stronger the implication that the unique dimorphy of *caulobacters* expresses a complex and sophisticated genetic heritage, and that dimorphy is of great significance to the success of *caulobacters* as they eke out their existence by competing for nutrients that are perpetually scarce.

In today's biology, we accept the notion that cells do not create genes; they copy them. The remarkably detailed molecular studies of *C. crescentus* development should help us recognize the parallel throughout the cell: some molecules in addition to DNA must be present for still other molecules to be synthesized and ordered. Like peptidoglycan and DNA, which can be polymerized only in a cell that has some of each, the cascades, feedback loops, protein phosphorylation pathways, and other controlling events, which occur during *C. crescentus* development, occur normally only in cells in which certain key events are already in progress and where certain key proteins are already in place. *C. crescentus* research, with an abundance of molecular detail, is contributing to cell biology an elegant lesson in the meaning of the biotic continuum.

Glossary

Chlamydia muridarum A mouse-adapted *Chlamydia* species.

Chlamydia pneumoniae The bacterium that causes community-acquired pneumoniae.

Chlamydia trachomatis The bacterium that is the most common cause of sexually transmitted disease and preventable blindness worldwide.

Elementary body The infectious but non-metabolically active form of *Chlamydia*.

Inclusion The intracellular vacuole in which all *Chlamydia* species differentiate and replicate within.

Lipid droplets Endoplasmic reticulum-derived lipid storage organelles that are a source of neutral lipids.

Reticulate body The noninfectious but metabolically active form of *Chlamydia*.

Sphingomyelin A Golgi-derived sphingolipid that usually consists of ceramide and phosphorylcholine.

Type III secretion system A secretion system present in Gram-negative bacteria that functions to deliver effectors directly from the bacteria into the host cytoplasm.

Abbreviations

CADD	<i>Chlamydia</i> protein associating with death domains;
CPAF	Chlamydial protease-like or proteosome-like activity factor;
EAE	Enzootic abortion of ewes;
EB	Elementary body;
EEA1	Early endosomal antigen;
EUO	Early upstream open reading frame;
GrgA	General regulator of gene transcription A;
HGT	Horizontal gene transfer;
IDO	Indolamine 2,3-dioxygenase;
Ig	Immunoglobulin;
IL	Interleukin;
Inc	Inclusion Membrane Protein;
INF-γ	Gamma interferon;
LCTs	Large cytotoxins;
LD	Lipid droplets;
LGV	Lymphogranuloma venereum;
MIF	Microimmunofluorescence assays;
MTOC	Microtubule organizing center;
MVBs	Multivesicular bodies;

Defining Statement

Chlamydiae are obligate intracellular bacteria that replicate within a nonacidified vacuole, termed the inclusion, which is actively modified by chlamydiae to promote their intracellular survival. To mediate their pathogenesis, chlamydiae secrete effector proteins into the host cytoplasm and inclusion membrane that directly target host signaling and trafficking pathways.

Introduction

Chlamydia is a Gram-negative obligate intracellular bacterium that is pathogenic for humans and a large variety of veterinary animal species. Chlamydiae replicate within a nonacidified vacuole, termed the inclusion, which is actively modified by chlamydiae to create a replication-competent intracellular compartment. Significant progresses in the understanding of the molecular mechanisms that mediate the pathogenesis of chlamydiae have been elucidated in the post-genomic era. It has become clear that chlamydiae secrete both type III secretion system (T3SS)-dependent and -independent effectors into the host cytoplasm to directly target and exploit basic host cellular signaling and trafficking pathways. The understanding of *Chlamydia* biology is being rapidly accelerated as a result of novel genetic tools, particularly newly developed transformation methodologies, and various expression and silencing vectors.

Taxonomy

Chlamydiae belong to the Chlamydiaceae family (order Chlamydiales) that contains a single genus *Chlamydia*. Since 1999, three new families have been classified within the order Chlamydiales. These include the families Parachlamydiaceae, Simkaniaceae, and Waddliaceae, all of which contain *Chlamydia*-like or environmental *Chlamydia* species. Currently, the genus *Chlamydia* contains 11 species: *Chlamydia trachomatis*, *Chlamydia muridarum* (formerly *trachomatis* mouse pneumonitis agent or MoPn), *Chlamydia suis*, *C. pneumoniae*, *C. psittaci* (formerly *psittaci* avian), *C. pecorum*, *C. abortus*, *C. felis*, and *C. caviae* (formerly *psittaci* GPIC), *Chlamydia avium* and *Chlamydia gallinaceae* (Sachse et al., 2014). It should be pointed out that, near the end of the last century, two genera were proposed for Chlamydiaceae: *Chlamydia* and *Chlamydophila*. However, that taxonomy received little support from chlamydial researchers.

Chlamydiae have a diverse range of hosts. Man is the only known host for *C. trachomatis*. In comparison, the host range of *C. pneumoniae*, once thought to be an exclusively human pathogen, has been extended to other mammals, amphibians, and reptiles. All other *Chlamydia* species primarily infect nonhuman animals and birds, although occasional zoonotic infections do occur. *C. suis* infects swine; *C. abortus* infects ruminants; *C. caviae* infects guinea pigs; *C. felis* infects cats; *C. pecorum* infects mammals such as cattle, koalas, sheep, and swine; *C. psittaci*, *C. avium* and *C. gallinaceae* infect birds.

Within the species *C. trachomatis*, there are two biovariants (trachoma and lymphogranuloma venereum, LGV) that are distinguished based upon their anatomical distribution and severity of disease. The trachoma biovars are further classified serologically into at least 20 distinct serovars. Chlamydiae of serovars A–C primarily infect ocular epithelial surfaces and are associated with endemic blinding trachoma, a leading cause of preventable blindness worldwide. Chlamydiae of serovars D–K infect the urogenital epithelial mucosa and are the most frequent cause of bacteria-caused sexually transmitted disease, but they can also cause inclusion conjunctivitis in adults, presumably by autoinoculation from a genital site of infection. The LGV biovars (serovars L1, L2, and L3) are also sexually transmitted and infect urogenital epithelial mucosal surfaces. However, unlike the trachoma biovars, which remain localized to mucosal surfaces, the LGV serovars are more invasive. The LGV serovars penetrate the submucosa, resulting in spread to the lymphatic system.

In humans, *C. pneumoniae* is primarily a respiratory pathogen that is a leading cause of community-acquired pneumonia. Additionally, *C. pneumoniae* has been linked with several chronic conditions such as coronary heart disease and is thought to be an added risk factor for the development of atherosclerosis. Finally, *C. pneumoniae* has been isolated from the brain of Alzheimer disease patients, but it is not clear what (if any) role this organism plays in the pathogenesis of the disease.

Developmental Cycle

Despite extreme diversity in tissue tropism, disease expression, and *in vitro* growth properties, all chlamydiae are characterized by a unique biphasic developmental cycle that alternates between two morphological and functionally distinct cell types: the elementary body (EB) and the reticulate body (RB) (Figure 1). The EB is the smaller developmental form measuring 0.3–5 µm in diameter. It is metabolically inert and is the infectious form of the bacterium. The physical features that define the EB include a highly condensed nucleoid structure as well as an extensively disulfide cross-linked outer membrane. In the absence of measurable amounts of peptidoglycan, a cell wall component that provides structural support to most other bacterial species, the cross-linking between cysteine-rich outer membrane proteins imparts structural rigidity to the EB. The properties of the EB facilitate the extracellular survival of the organism at the initial infection or transmission stages and mediate internalization, and hence infection, of the organism into host eukaryotic cells.

Figure 1 Chlamydial developmental cycle. The developmental cycle begins with the attachment and parasite-mediated endocytosis of the elementary body (EB). After internalization the EB is found within a membrane-bound vacuole, termed the inclusion. By 2 h p.i., the EB differentiates into the reticulate body (RB) and is trafficked to the peri-Golgi region of the host cell. Between 8 and 10 h p.i. the RBs begin to replicate and between 18 and 24 h p.i. some of the RBs begin to dedifferentiate back into infectious EBs. The cycle ends with either host cell lysis or extrusion of the inclusion from the infected cell, resulting in release of infectious EBs. All *Chlamydia* species undergo a similar developmental cycle. However, the time it takes to complete the cycle may vary from 36 to 96 h depending on the particular species.

In contrast to the EB, the RB is larger at approximately 1 μm in diameter; it is also metabolically active and noninfectious. In addition, the nucleoid is more diffuse within the bacteria, making the DNA accessible to the transcriptional and replication machineries. Furthermore, the outer membrane is less cross-linked, which makes the RB much more fragile than the EB and enables the replication of the organism. Whereas the EB functions in extracellular survival and internalization, the RB is the metabolic and replicative form and thus functions in intracellular survival and replication.

The developmental cycle is initiated by the attachment and internalization of the EB into the host eukaryotic cell, resulting in the envelopment of the EB in a membrane-bound vacuole, which has been termed the inclusion (Figure 1). The bacteria remain confined within the inclusion during the entire developmental cycle. Within the first several hours postinfection (p.i.), the internalized EBs differentiate into RBs. Depending on the specific strain or species, the newly generated RBs replicate by binary fission starting between 6 and 18 h p.i. The developmental cycle is asynchronous. While some RBs continue to divide, others begin to differentiate back into EBs, resulting in a mixture of EBs and RBs. Since RBs are localized adjacent to the inclusion membrane, while EBs are localized to the lumen of the inclusion, it has been proposed that detachment from the inclusion membrane and inactivation of the T3SS apparatus may signal the dedifferentiation process. As the organisms replicate, the original inclusion membrane increases in size to accommodate the increasing numbers of organisms. By the end of the cycle, the inclusion occupies the majority of the host cytoplasm. The increase in size of the inclusion is likely due to incorporation of both *Chlamydia*- and host-derived proteins into the expanding inclusion membrane. The cycle ends with either activation of cysteine proteases and host cell lysis or extrusion of the inclusion out of the cell by an actin- and myosin-dependent mechanism. Release of newly generated infectious EBs that can infect neighboring cells ensures continuation of the chlamydial developmental cycle.

All *Chlamydia* species undergo a similar developmental cycle that differs primarily in the time it takes to complete the cycle, which can range from 36 h for the fast-growing *C. muridarum* strains to 96 h for the slower-growing *C. pneumoniae* strains. The *C. trachomatis* strains fall in the middle of this spectrum with cycle lengths of 44–72 h depending on the specific biovar or serovar, and culture condition.

Whole genome microarray and RT-PCR analyses of specific subsets of chlamydial genes revealed that chlamydiae regulate the transcription of their genome in a temporal fashion. Three classes of gene transcription were identified that correlate with morphological aspects of the developmental cycle. Expression of 'early' genes is detected from 1 to 6 h p.i. 'Early' genes are likely to include genes involved in early metabolic processes, nutrient uptake, inclusion biogenesis, and EB to RB differentiation. Expression of 'mid cycle' genes is detected between 6 and 18 h p.i., and these genes are likely to be involved in replication and metabolic processes. Finally, expression of 'late' genes is detected 18 h and 24 h p.i. 'Late' genes include those involved in the dedifferentiation of RBs to EBs. Although the chlamydial genome encodes two alternative sigma factors, temporal regulation of chlamydial gene transcription is not regulated by these alternative sigma factors. Other types of regulation, such as response to stress, heat, nutrients, and host inflammatory cytokines, are superimposed upon the global temporal regulation.

Intracellular Survival

As obligate intracellular bacteria, chlamydiae have evolved highly successful strategies to promote and maintain their intracellular lifestyle including specific mechanisms to (1) gain entry into host cells, (2) avoid or prevent degradation by degradative lysosomal enzymes, (3) obtain nutrients and biosynthetic precursors while sequestered within a protected niche, and (4) evade host immune detection and destruction. Importantly, chlamydiae accomplish these tasks while sequestered within the protected environment of the inclusion through the exploitation of host signaling and trafficking pathways. Because *Chlamydia* species display such differences in tissue tropism and *in vitro* growth properties, and because of differences arising from experimental protocols, observations made about one species or serovar may or may not apply to all species.

Entry

For most *Chlamydia* species, columnar epithelial cells, which are nonprofessional phagocytes, are the primary sites of infection. However, other cell types can be naturally infected by some species. For example, the LGV biovars of *C. trachomatis* can replicate in monocytes/macrophages, while *C. pneumoniae* can replicate in many different cell types including epithelial, endothelial, and smooth muscle cells, and monocytes/macrophage. Chlamydiae enter nonprofessional phagocytes by a process that has been defined as 'parasite-mediated' endocytosis since it is 10–100 times more efficient than the uptake of inert particles such as latex beads or opsonized yeast. *In vitro*, multiple modes of entry have been documented including both clathrin- and non-clathrin-mediated endocytosis, microfilament-mediated phagocytosis, microfilament-independent pinocytosis as well as lipid raft-mediated endocytosis. Although different modes of entry have been established for *Chlamydia* species, a novel host cell actin-dependent entry mechanism has recently been reported. In this model, attachment of the EBs to the host cell surface is followed by the translocation of the T3SS effectors, translocated actin recruiting protein (Tarp) and translocated early phosphoprotein (TepP), into the host cell. Upon translocation, Tarp and TepP are sequentially phosphorylated by host cell kinases and concentrate on the cytoplasmic side of the eukaryotic plasma membrane at sites of EB attachment in *C. trachomatis*-infected cells. Tarp is an actin-binding protein that facilitates localized actin recruitment and polymerization at sites of EB entry. TepP likely serves as a downstream effector in this process. Subsequent to the phosphorylation of these secreted proteins, there is activation of host Rho GTPases, which are small ras-like GTPases that regulate actin dynamics. In *C. trachomatis*-infected cells, Rac1 is activated, while in *C. caviae*-infected cells, both Rac1 and Cdc42 are activated. The activation of Rho GTPases leads to the recruitment of several host proteins, including WAVE2, Abi-1, and Arp2/3, which are critical molecules in actin signaling and polymerization, to sites of EB attachment. Collectively, the activation and recruitment of these host signaling molecules, and others including another small GTPase, Arf6, leads to localized actin polymerization and cytoskeletal rearrangements that mediate the internalization of EBs. For other species, such as *C. pneumoniae*, the attachment of EBs induces the activation of other host signaling pathways including phosphatidylinositol-3-kinase (PI3K)-dependent and ERK1/2-dependent signaling pathways that are important for the entry of *C. pneumoniae* EBs.

Early Intracellular Events

During the first 2–3 h following internalization several critical events occur that are dependent on early *de novo* chlamydial gene expression. One of these critical events is EB to RB differentiation. Morphologically, differentiation is manifested by the reduction of the disulfide-linked outer membrane, the decondensation of the nucleoid, and an increase in size of the bacterium. The decondensation of the chlamydial chromatin plays an important role in silencing gene transcription in EBs. Two basic histone-like proteins Hc1 and Hc2 are thought to play critical roles in this process as overexpression of chlamydial Hc1 in *Escherichia coli* leads to condensation of the *E. coli* chromosome, gene silencing, and death. However, since Hc1 is expressed throughout the developmental cycle, degradation of Hc1 cannot be a mechanism that triggers DNA unwinding. Insights into this intriguing dilemma were revealed when researchers found that the death induced by overexpression of Hc1 in *E. coli* could be rescued by the overexpression of a second chlamydial gene product, CT804. CT804 is predicted to encode a kinase that shares homology to *E. coli* *IspE*, an enzyme that functions in a nonmevalonate pathway of isoprenoid biosynthesis. Currently, researchers believe that a metabolite of the pathway may act as a competitive inhibitor that blocks the DNA binding activity of Hc1, thereby allowing the DNA to unwind and enabling the initiation of the developmental transcriptional program.

EUO is one of few genes that are transcribed almost immediately (<1 h p.i.) after EB entry into the cell. By binding selectively to later gene promoters, EUO allows the transcription of early genes. Expression of early genes may also be facilitated by the newly identified transcription factor GrgA synthesized during the mid-late developmental stages.

Together with the physical changes in the organism, there are also critical interactions between the bacteria and the host that are established during this time period including the avoidance of lysosomal fusion, the intracellular redistribution of EBs, and the interception of host-derived secretory vesicles.

Avoidance of lysosomal fusion

One of the obstacles that all intracellular bacteria encounter is the harsh degradative environment of host cell lysosomes, which a bacterial pathogen would normally encounter upon endocytosis and trafficking along the default endocytic/lysosomal pathway. Bacterial pathogens have evolved unique mechanisms to circumvent their destruction in lysosomes. Some alter their phagosomal

maturation at an early prelysosomal stage such that they avoid fusion with lysosomes, while others like *Chlamydia* escape the default endocytic/lysosomal pathway and replicate in vacuoles that share properties with other host organelles, such as secretory organelles. Chlamydiae exit the classical endocytic/lysosomal pathway early during the developmental cycle as evidenced by absence of classical endocytic markers by processes dependent on early chlamydial protein expression. Incs, chlamydial proteins targeted to the inclusion membrane, likely play important roles in the inhibition of lysosomal fusion. Structurally, Incs mimic SNARE proteins essential for membrane fusion in the host cell.

Translocation of EBs

By 2–3 h p.i. EB-containing vacuoles are transported from the periphery of the cell and aggregate at the peri-Golgi region or the region of the cell that corresponds to the microtubule organizing center (MTOC) by processes that are dependent on early chlamydial gene expression. During this initial infection period, at least 60 ‘early genes’ are expressed. Several of these early expressed genes are localized to the inclusion membrane and thus are likely candidates to facilitate the redistribution of EBs.

Host factors are also required for the intracellular trafficking of the EB-containing early inclusion. Some chlamydiae exploit microtubule-dependent host trafficking pathways to mediate their intracellular redistribution. Consistent with the trafficking of EBs toward the minus-ends of microtubules, the redistribution of EBs has been shown to be dependent on dynein, a minus-ended microtubule-dependent motor protein. Most dynein-dependent trafficking pathways in the cell require the assistance of dynactin, a multiprotein complex that facilitates cargo binding to dynein. Interestingly, although the transport of EBs requires dynein and at least one component of dynactin, p150^{glucd}, localizes to inclusions, trafficking does not require dynactin. These data suggest that EBs exploit a novel dynein-dependent but dynactin-independent transport pathway to facilitate their redistribution within the eukaryotic cell. Protein tyrosine kinases Fyn and Src are also required for the trafficking of chlamydial inclusion. Fyn and Src are recruited to the inclusion where they directly interact with Incs.

Chlamydia-mediated remodeling of the inclusion is absolutely essential for the intracellular survival of chlamydiae. In the absence of early chlamydial gene expression all of these early events fail to occur and eventually the chlamydiae will be trafficked to host lysosomes and destroyed.

Nutrient and Biosynthetic Precursor Acquisition

Chlamydiae are auxotrophic organisms that rely on their eukaryotic host for essential nutrients such as nucleotides (including ATP, GTP, UTP but not CTP or any of the deoxynucleotides), amino acids, and a variety of host-derived lipid species including glycerophospholipids, cholesterol, sphingomyelin, and neutral lipids. Chlamydiae acquire host-derived lipids by targeting both vesicular- and non-vesicular-mediated host trafficking pathways. Beginning by 2 h p.i., coincident with the redistribution of EBs to the peri-Golgi region, the inclusion becomes competent to fuse with a subset of Golgi-derived exocytic vesicles containing endogenously synthesized sphingomyelin and cholesterol. Subsequent to this discovery, it was revealed that chlamydiae also acquire sphingomyelin from the delivery of multivesicular bodies (MVBs) that originate from late endosomes to the inclusion. Chlamydiae also recruit lipid droplets (LD) to the inclusion. LDs are ER-derived lipid storage organelles that are a source of neutral lipids. Recent work has shown that IncD recruits host lipid-binding proteins GBF1 and CERT to acquire host sphingomyelin. This process likely also involves Fyn and Src, and the Raf/MEK/ERK signal transduction pathway.

Exiting

Two alternative exiting mechanisms have been demonstrated for *Chlamydia*: lysis and extrusion. The lytic pathway is initiated with a loss of the inclusion integrity, which is followed by rupture of nucleus and plasma membrane. Lysis requires proteases and a rise of intracellular calcium concentration. The extrusion pathway causes the release of intact inclusions, and requires actin polymerization; neuronal Wiskott–Aldrich syndrome protein, myosin II, and Rho GTPase are all required for extrusion.

Virulence Factors

Intracellular pathogens exploit basic host cellular processes to mediate their entry and intracellular survival. Since chlamydiae remain sequestered within the inclusion, proteins that function to subvert host cellular processes need to directly access the host cytoplasm. Bioinformatics and heterologous expression systems have been used to demonstrate that chlamydiae express two categories of proteins that directly access the host cytoplasm: soluble, secreted proteins that are translocated directly into the host cytoplasm and membrane-anchored proteins that localize to the inclusion membrane. In addition, like other bacteria, chlamydiae carry a plasmid that encodes virulence factors. At least one plasmid-encoded protein (Pgp3) is targeted to the host cell cytoplasm.

The plasmid

All *Chlamydia* species carry a plasmid. Loss of the so called ‘cryptic’ plasmid in both *C. trachomatis* and *C. muridarum* results in attenuation of pathogenicity, as demonstrated in a nonhuman primate model and a mouse model, respectively. The plasmid is highly conserved in these two bacteria, and carries 8 open reading frames (ORFs), pgp1-8. Rapid revelation of the roles for these

ORFs has been made possible by the recently developed chlamydial transformation technique. Pgp1, 2 and 6 and the coding sequence of pgp8 serve as plasmid maintenance factors, Pgp4 as a transcriptional regulator for some 20 chromosome-encoded virulence determinants, and Pgp3, 5, 7 and 8 as dispensable for chlamydial growth in vitro.

Pgp3 is secreted into the host cell cytoplasm likely through a T3SS-independent mechanism. Several lines of evidence support a role of Pgp3 plays a critical role in promoting chlamydial pathogenicity. First, recombinant, LPS-free Pgp3 strongly induces IL-8 and TNF- α production from macrophages. Second, X-ray crystallography reveals that Pgp3 is a trimeric protein with the C-termini of the subunits forming a structure resembling that of TNF- α , providing a structural basis for Pgp3 to activate the TNF receptor-mediated inflammatory pathways. Third, *C. muridarum* carrying a plasmid with inactivated *pgp3* gene show normal growth but cannot induce hydrosalpinx in mice.

Chromosome-encoded Virulence Factors

T3SS

Many Gram-negative bacterial pathogens, including *Chlamydia* species, share a unique virulence trait, a T3SS. T3SS is a specialized needle-like secretion system designed to translocate proteins from the bacteria directly into the host cell cytoplasm. T3SS effectors have been shown to modulate a large variety of host functions and facilitate many aspects of bacterial pathogenesis including entry, vacuolar biogenesis, intracellular trafficking, and inhibition or induction of host apoptotic pathways. Although electron micrographs obtained in the early 1970s depicted structures that resembled T3SS needle structures originating from the bacteria and extending through the inclusion membrane, genetic evidence that *Chlamydia* species encoded a T3SS was not obtained until 1997, when four genes with significant homology to known T3SS genes were identified in *C. caviae*. The following year, genomic sequence analysis revealed that *C. trachomatis* encoded within their genome a complete, albeit abbreviated, T3SS.

T3SS consist of a conserved core secretory apparatus, T3SS-specific chaperones, mobile translocation proteins, and a highly diverse set of secreted effectors. Because the core secretory apparatus and associated accessory molecules have retained DNA sequence conservation, bioinformatics approaches have successfully identified genes homologous to these conserved components in all *Chlamydia* species. Based upon comparison to the DNA sequences of T3SS in other bacteria, chlamydiae do not appear to encode the entire complement of T3SS genes, although they do encode enough of the components to produce a functioning T3SS. Chlamydiae likely encode T3SS structural components that have yet to be identified by conventional approaches due to divergence in DNA sequences. In support of this hypothesis, CdsF, which shares no sequence homology with other T3SS proteins, was identified as a possible functional homologue of the needle subunit protein SctF. Interestingly, there is no evidence that *Chlamydia* have acquired these genes through horizontal gene transfer (HGT), as is thought to be the case for T3SS in other facultative pathogenic bacteria. Although loosely organized into four genomic locations, genes encoding the T3SS are scattered throughout the genome. In addition, there are no differences in GC content of the T3SS-encoded genes as compared to the rest of the genome, nor is there evidence of associated insertion or transposon-like elements.

T3SS effectors

In contrast to proteins that make up the secretion and translocation apparatus, effector proteins that are secreted into the host cytoplasm generally share no sequence homology as they normally execute functions specific to the bacterial pathogen and host cell type. Therefore, it has been more difficult to identify chlamydial effectors by DNA sequence homology alone. However, progress has been made in the identification and characterization of several important chlamydial type III effectors. By taking advantage of heterologous T3SS systems of *Yersinia*, *Salmonella*, and *Shigella*, several researchers have confirmed T3SS-dependent secretion of specific chlamydial proteins or have identified novel effectors among the numerous 'hypothetical ORFs' present in the various chlamydial genomes. To date, there are about 80 predicted T3SS effectors including a number of Incs, Tarp, TepP, components of the T3SS apparatus (CopN, CopB, CopB2), CT847, Pkn5 (a serine/threonine protein kinase), *Chlamydia* protein associating with death domains (CADD), and numerous hypothetical ORFs.

Incs were originally identified in the pregenomic era through the isolation of proteins recognized by convalescent sera from guinea pigs infected with *C. caviae*. Upon completion of the genomic sequences from several *Chlamydia* species, based upon the presence of the signature hydrophobic motif, it was determined that *Chlamydia* species are predicted to encode 60–80 different Incs. Except for the conserved hydrophobic motif, Incs share no homologies with any other proteins in the databases nor do they share extensive homologies between themselves. In fact, *Chlamydia* species appear to express different complements of Incs. Furthermore, microinjection studies using domain-specific antibodies have demonstrated that many of the Incs directly access the host cytoplasm, making them likely candidates to exploit host cellular signaling and trafficking pathways through direct interaction with host proteins. Finally, Incs are expressed at all stages of the developmental cycle, suggesting that they may function at multiple times throughout infection. Biological roles for several inclusion-localized proteins have been proposed. For example, IncA is thought to promote homotypic vesicle fusion between *Chlamydia*-containing vesicles via either IncA–IncA interactions or the recruitment of host soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs) to the inclusion. Consistent with a role in homotypic vesicle fusion, clinical *C. trachomatis* isolates that do not express IncA replicate in multiple nonfused inclusions. *C. trachomatis* IncD interacts with lipid-binding proteins of the host to acquire lipids. IncG has been shown to recruit mammalian 14-3-3 β to the inclusion. 14-3-3 β is a phosphoserine binding protein that plays multiple roles in cell signaling and cell survival. The recruitment of 14-3-3 β to the inclusion contributes to the ability of chlamydiae to inhibit cellular apoptosis by sequestering and inhibiting the pro-apoptotic protein BAD at the inclusion. Finally, two Incs have been shown to recruit Rab

GTPases to the inclusion. Rab GTPases are small ras-like GTPases that play critical roles in vesicular-mediated trafficking pathways. *C. trachomatis* Inc CT229 recruits Rab4 to the inclusion, while *C. pneumoniae* Inc Cpn0585 interacts with multiple Rab GTPases, suggesting that chlamydiae may exploit Rab-dependent trafficking pathways to facilitate their intracellular trafficking or to modulate the identity of the inclusion.

CopN, a homologue of *Yersinia* YopN and component of the T3SS apparatus, CT147, and Cap1, a CD8⁺ T cell epitope, are also localized to the inclusion membrane but lack the signature hydrophobic profile of Incs. CT147 is an early expressed inclusion localized protein that is homologous to the mammalian early endosomal antigen (EEA1). EEA1 contains a 'FYVE' domain that interacts with phosphatidylinositol (Ptd)-3-P, regulating tethering of early endosomes, and a separate domain that interacts with Rab5, regulating fusion of early endosomes. Interestingly, CT147 contains only the 'FYVE' domain that interacts with Ptd-3-P, suggesting that CT147 may function to tether early endosomes to the inclusion but, since it lacks the Rab5 interacting domain that promotes fusion, fusion with early endosomes is prohibited. However, the specific function of CT147 remains to be determined.

CADD was identified through a bioinformatics approach due to its homology with mammalian death domain receptors of the tumor necrosis factor (TNF) family. It has been shown to interact with several human death receptor domain family proteins including TNFR1, Fas, DR4, and DR5, and it partially co-localizes with Fas adjacent to the inclusion membrane in infected cells. Although ectopic expression of CADD induces host cell apoptosis, neither endogenous expression of CADD nor localization of Fas to the inclusion is sufficient to induce apoptosis in *Chlamydia*-infected cells. These conflicting results suggest that the ability to influence the host cell apoptotic pathways may be due to the specific localization of CADD, and therefore the exact role that endogenous CADD plays has not been elucidated.

Secretion of CADD into host cells can be inhibited by a compound designated C1. However, whether CADD is a T3SS effector is not entirely certain since C1 and other salicylidene acylhydrazide-based T3SS inhibitors also inhibit iron metabolism. Likewise, other T3SS effectors proposed solely based on the use of salicylidene acylhydrazides have yet to be affirmed by additional experimentation.

Other secreted effectors

Several *Chlamydia* species encode several partial and complete ORFs that share significant homology to the catalytic domains of large cytotoxins (LCTs) produced by *Clostridium difficile*. LCTs inhibit the activity of Rho family GTPases, key regulators of the actin cytoskeleton. Some chlamydial strains are cytopathic to the host when infected at high multiplicities of infection in a phenomenon that has been termed 'multiplication independent immediate cytotoxicity'. Interestingly, there is a direct correlation between the ability to induce cytotoxicity and the number of cytotoxin-like genes that a strain encodes. More importantly, the immediate toxicity induced by chlamydiae is phenotypically indistinguishable from cells that have been exposed to LCTs. In both cases, there is a dramatic reorganization of the cytoskeleton that is manifested with the disassembly of actin stress fibers, which results in rounding up of the cells. Although the cytotoxins are expressed during later parts of the developmental cycle, it is thought that they are present in EBs as preformed effectors and they function early during the developmental cycle. One possible model suggests that the cytotoxins act to inhibit host Rho GTPases at sites of chlamydial entry. Alternatively, the cytotoxins also share homologies to *E. coli* lymphostatin protein (LifA) and therefore may play a role in immunosuppression.

Chlamydial protease-like factor (CPAF) is a *Chlamydia*-encoded serine protease found in the cytoplasm of infected cells. Cleavage of numerous host proteins by CPAF has been reported in the literature. However, it is now clear that those reports were results of experimental artifacts arising during sample preparation. Although the physiological substrates of CPAF remain at large, it likely functions as an important virulence factor since antibody against CPAF can neutralize the infectivity of EBs, and immunization of mice with CPAF has been shown to elicit a protective immune response.

Host Tropism

Surprisingly, comparative genomic analysis revealed that the human pathogen *C. trachomatis* and the mouse pathogen *C. muridarum* share near genomic synteny. Even more strikingly, *C. trachomatis* serovar A, an oculotropic serovar, and *C. trachomatis* serovar D, a genitotropic serovar, share 99.6% DNA sequence identity and yet display different tissue tropisms *in vivo*. Most of the strain-specific genes are localized to a single region of the chromosome, which has been termed the hypervariable plasticity zone (PZ). Several of the genes that are localized to the PZ encode tryptophan synthase and the cytotoxins, both of which are thought to play crucial roles in host and tissue tropism. First, genes encoding functional tryptophan synthase are present in the PZ of only *C. trachomatis* genital tract and not ocular species. The genes are completely absent from *C. muridarum*. None of the *C. trachomatis* strains are able to produce tryptophan, an essential amino acid, from most tryptophan metabolic precursors. However, the genital tract *C. trachomatis* strains that express tryptophan synthase are capable of generating tryptophan, from exogenously added indole, whereas strains deficient for this enzyme cannot. The important host proinflammatory molecule INF- γ acts in part to inhibit chlamydial growth by the induction of indoleamine 2,3-dioxygenase (IDO), which functions to degrade tryptophan. Therefore, genital tract *C. trachomatis* strains that can synthesize tryptophan from indole, perhaps derived from the vaginal flora, may use this as a mechanism to overcome INF- γ -induced IDO activity. As such, tryptophan synthase is considered a virulence factor that differentiates the ocular and the genital tract serovars of *C. trachomatis* as well as differentiates the human genital tract *C. trachomatis* strains from murine *C. muridarum*.

Differences in susceptibility to INF- γ also distinguish *C. trachomatis* strains from *C. muridarum*. Susceptibility to INF- γ correlates with the presence or absence of cytotoxins in each of the respective genomes. The growth of *C. trachomatis*, which lacks or contains truncated forms of the cytotoxins, is inhibited by INF- γ , whereas the growth of *C. muridarum*, which contains three complete copies of the cytotoxins, is not. Recent evidence suggests that differential susceptibility to INF- γ may be due to INF- γ -inducible GTPases such as the p47 GTPase, *ligp1*, a mouse-specific immune regulator that inhibits the growth of intracellular pathogens. *ligp1* contains motifs similar to YopT targeting sequences. Since the chlamydial cytotoxins share similarities with YopT, the cytotoxins present in *C. muridarum* may target and inhibit *ligp1*, thus providing a model for how *C. muridarum* may resist the inhibitory effects of INF- γ . Consistent with this hypothesis, knockdown of *ligp1* makes *C. trachomatis* strains, which do not express the cytotoxins, less susceptible to INF- γ -mediated growth inhibition. Based upon these observations, the prevailing model suggests that the diversity in the PZ arose to counteract species-specific host immune effectors such as INF- γ .

Clinical Disease, Diagnosis, and Treatment

Although chlamydiae cause a wide range of diseases in many different host species, most sequelae resulting from chlamydial infections are primarily due to the fibrosis and tissue damage that results from chlamydial-mediated induction of host proinflammatory cytokine responses that can occur during repeated or persistent infections.

C. trachomatis: Trachoma

C. trachomatis servars A, Ba, Bb, and C infect ocular mucosal surfaces, causing trachoma, the leading cause of preventable blindness worldwide. Although virtually absent from industrialized countries, trachoma is still endemic in tropical and subtropical areas with poor hygienic conditions, including North Africa, the Middle East, and Northern India. The disease is transmitted from human to human through fomites. It may also be potentiated by the transfer of human secretions by flies. Infection begins as conjunctivitis, which is followed by follicle formation. Scarring and distortion of the eyelids may be caused by subsequent follicle rupture, which in turn causes in-turning of the eyelids. In-turning of the eyelid causes the eyelashes to scrape the cornea, which causes physical damage to the cornea. It is the physical damage to the cornea that ultimately leads to blindness. Therefore, blindness does not result from an acute infection, but rather results after repeated or persistent infections.

Diagnosis of trachoma is made by isolation of the chlamydial organism from conjunctival scrapings or identification of inclusions in epithelial cells derived from conjunctival scrapings. Trachoma is still a disease associated with poverty and poor hygienic conditions. An eradication program known as the SAFE strategy has been in place in endemic countries to try to eliminate the disease. The SAFE strategy includes surgery to repair damaged eyelids, antibiotic treatment to eliminate the bacteria, face cleanliness to improve personal hygiene, and environmental improvements to reduce the fly population to reduce bacterial spread. The disease is currently treated with antibiotics such as doxycycline and azithromycin. The latter is more expensive but more convenient, as a single dose is all that is required.

C. trachomatis: Urogenital Tract Infections

Serovars D, E, F, G, H, I, J, and K of *C. trachomatis* infect the columnar epithelial cells of the urogenital tract. The epithelium of the respiratory tract of newborns can be infected after passing the birth canal of infected mothers. Each year, close to 90 million new cases are reported, making *C. trachomatis* infections the leading bacterial cause of sexually transmitted disease. There is evidence that the gastrointestinal tract is another naturally infected site. *C. trachomatis* causes a wide variety of disease manifestations in both men and women. These include adult and infant inclusion conjunctivitis (which rarely, if ever, leads to blindness), pneumonia, salpingitis, cervicitis, female urethral syndrome, postpartum endometritis, male urethritis, epididymitis, and arthritis. Fibrosis and scarring in the urogenital tract are the hallmarks of chlamydial infections due to the elicitation of a strong proinflammatory host cell response to the invading bacteria. Scarring causes the devastating sequelae that develop upon repeated or persistent chlamydial infections. Due to the asymptomatic nature of most chlamydial infections, chlamydial infections often go undiagnosed and untreated. In women, untreated chlamydial infections can lead to pelvic inflammatory disease, ectopic pregnancy, and infertility. In addition, chlamydial infections may lead to increased susceptibility to HIV infection.

Laboratory diagnosis can be made by isolation of the chlamydial organisms from cervical or urethral swabs or by visualizing infected cells with direct fluorescence antibody tests, enzyme-linked immunoassays for antigen, or nucleic acid detection. Nucleic acid amplification tests using either self-collected vaginal swabs or voided urine are much more sensitive than culture for detecting genital *Chlamydia* infections in women. Similar to ocular infections, genital tract infections are treated with tetracyclines or macrolides.

Lymphogranuloma Venereum

The LGV serovars (L1, L2, and L3) of *C. trachomatis* also infect mucosal surfaces of the urogenital tract. However, in contrast to infections by the trachoma, which remain localized to the epithelium, the LGV serovars infiltrate the submucosa, resulting in

infection of the lymphatic drainage system and a more systemic disease. Common in tropical areas of Asia, Africa, and Central America, LGV has been virtually eliminated in the United States, but an epidemic has been taking place among men who have sex with men in Europe for more than a decade. In the initial stages of infection, asymptomatic primary lesions develop on the labia, vagina, cervix, or penis and may result in mild proctitis. If the infection is not diagnosed and treated, lymphadenopathy in the nodes draining the site of primary infection (usually inguinal and femoral) may form. The nodes may rupture, resulting in chronic draining fistulas. At this stage, the disease can take two courses, the abscesses will either resolve or the disease will become systemic, which can result in fever, myalgia, and headache. Chronic inflammation and scarring may occur in some cases. Diagnosis is made upon isolation of the bacteria from either a primary lesion or aspirated pus, or by microimmunofluorescence assays (MIF).

C. pneumoniae

C. pneumoniae is a newly recognized species that is primarily a respiratory pathogen. Although the species was first isolated in 1965 from a child's conjunctiva during a trachoma vaccine trial study in Taiwan, it was not considered a respiratory pathogen until 1983, when it was isolated from the pharynx of a pharyngitis patient. The original isolate, TW-183, and the respiratory isolate, AR-39, were subsequently discovered to be the same organism, and thus have become known as the TWAR isolates. Infections by *C. pneumoniae* cause 10% of all community-acquired pneumonia infections and 5% of all bronchitis cases. Although most clinical manifestations are not easily distinguishable from other atypical pneumonias (nonproductive cough, headache, and malaise), there are several clinical signs that are more typical of infections caused by *C. pneumoniae*. These include a subacute onset and the presence of pharyngitis during the initial stages of infection. There may also be a biphasic pattern with resolution of the pharyngitis prior to the development of bronchitis. Finally, the presence of a prolonged cough and the absence of fever are also typical of *C. pneumoniae* infections. Most infections are mild or asymptomatic and do not require hospitalization. Despite antibiotic treatment, recovery is often slow with persistence of a cough for 2–6 weeks. All age groups are at risk; however, respiratory disease is most common among children 5–14 years old. The majority of adults are seropositive for *C. pneumoniae* antibody titers. These data suggest that by the time most people reach adulthood, they have been infected with *C. pneumoniae* at least one time during their life.

Laboratory diagnosis for respiratory infection is often unreliable due to the absence of well-standardized and commercially available diagnostic tests. The most common diagnostic test used involves serologic detection of *C. pneumoniae*-specific antibodies by MIF. *C. pneumoniae* infection is positively diagnosed with a single immunoglobulin (Ig)M titer greater than or equal to 1:16 or a fourfold increase in the IgG titer. In primary infections, *C. pneumoniae*-specific IgM and IgG titers do not appear until 2–3 weeks and 6–8 weeks after infection, respectively. Therefore, most physicians will prescribe antibiotic treatment that is effective against most bacteria-caused atypical pneumonias prior to a definitive diagnosis. Typically, antibiotic therapy consists of a macrolide such as azithromycin or clarithromycin. If a definitive diagnosis of *C. pneumoniae* is made, antibiotic therapy is usually switched to a 10–14 day course of doxycycline. *C. pneumoniae* infection may be linked to a variety of chronic inflammatory conditions such as asthma, atherosclerosis, myocardial infarctions, and multiple sclerosis.

C. muridarum

C. muridarum was isolated from a normal mouse. The organism causes pneumonia in intranasally inoculated mice, and had been classified as a separate biovar of *C. trachomatis* until just prior to the new millennium, and continued to be frequently referred as *C. trachomatis* mouse pneumonitis agent in the literature for a few more years into the new millennium. *C. muridarum* has been a commonly and a very useful organism for modeling human urogenital *C. trachomatis* infection in mice.

C. psittaci

C. psittaci is a common avian pathogen and causes 'chlamydiosis'. In the past, infections of psittacine birds were termed 'psittacosis' and infections of wild or domestic fowl were called 'ornithosis'. Because the diseases caused are so similar, the term 'chlamydiosis' is used for infections in all birds. More than 130 species of birds are known to be infected with *C. psittaci*. Clinical signs vary between the different bird species. However, early signs may include dyspnoea, sinusitis, unilateral conjunctivitis, and diarrhea. During an acute infection, egg production may be reduced. In addition, weight loss, reduced body temperatures, dehydration, and loss of appetite may also be present. Morbidity and mortality rates may be as high as 50–80% and 30%, respectively. Presumed diagnosis may be made on physical examination and history.

Definitive diagnosis of avian infections can be made by isolation of the organism and identification of inclusions in tissue culture cells or through the direct identification of the organism in infected tissue samples. Serological tests are not widely used for diagnosis. Chlortetracycline, delivered in the bird's food supply, is the antibiotic of choice. Oxytetracycline, doxycycline, and enrofloxacin are also used to treat infected populations. Quarantine and antibiotic treatment of imported birds are common control measures used to prevent spread of *C. psittaci* infections.

C. psittaci is a zoonotic pathogen. Manifestations of human infection can range from asymptomatic to a systemic toxic syndrome without respiratory infection. Common clinical signs include fever, chills, muscular aches and pains, and severe headaches. Due to the introduction of bird feed containing antibiotics and a 30 day quarantine period for imported birds, the cases of human *C. psittaci*

infections have dramatically decreased, with less than 50 confirmed cases being reported per year. People most at risk include pet shop and poultry industry workers.

Diagnosis *C. psittaci* infection is made by either isolation of the organism by culture, which is often not done due to the infectious nature of the organism, or a fourfold increase in *C. psittaci*-specific antibody titers. The treatment of choice is a 10–21 day regimen of tetracycline or doxycycline.

C. abortus

C. abortus infects the genital tracts of ruminants (sheep, cattle, and goats) and mostly causes abortions. Infections by *C. abortus* can also cause stillbirths and the delivery of weak full-term newborns. *C. abortus* infections are the most common cause of abortions in sheep, known as ovine enzootic abortion (OEA) or enzootic abortion of ewes (EAE). The organism is usually transmitted during lambing seasons, as infected animals undergoing abortions secrete large amounts of organisms in placental tissues, uterine discharges, and in feces. In the initial stages of infection, the organism is found in the main organs of the ewe. Infection remains subclinical until the last 4 weeks of pregnancy, when abortions occur. At this time, the placenta becomes infected, while the organism is cleared from the other parts of the animal. The fetus becomes infected, leading to death and subsequent abortion. Infected ewes generally recover with their subsequent fertility unaffected.

Diagnosis is made by identifying the bacteria in impression smears of placental cotyledons, by isolation of the organism by passage in tissue culture cells, and by detection of *C. abortus*-specific antibodies. Infections can be treated with oral chlortetracycline if administered prior to the appearance of the second chlamydia. However, a more effective treatment plan includes intramuscular injections of oxytetracycline. *C. abortus* infections are controlled by management procedures and by vaccination.

Human infection due to exposure to aborting sheep has been documented and can lead to abortion or severe respiratory disease in nonpregnant individuals.

C. felis

Infection by *C. felis* causes conjunctivitis, rhinitis, or pneumonia in cats. Although cats of all ages are susceptible to infection by *C. felis*, infection is more common in young kittens (5–12 weeks old). Clinical signs include fever, depression, sneezing, anorexia, coughing, occasional pneumonia, and serous discharge from the eyes and nose. *C. felis* infection of humans has been documented but it is rare. If left untreated, infections often persist for 6–8 weeks. Treatment usually involves both topical antibiotics in the form of eyedrops or ointment and oral antibiotics for 6–8 weeks. Feline vaccines exist that help reduce the severity of clinical disease.

C. pecorum

C. pecorum infections occur in some species of mammals including cattle, sheep, goats, koalas, and swine. Depending on the specific biotype, clinical symptoms may include conjunctivitis, polyarthritis, pneumonia, abortion, encephalitis, and enteritis. In cattle, clinical signs also include metritis, salpingitis, and infertility. Laboratory diagnosis is difficult because of difficulties in growing the organisms in culture and cross-reactivity of antibodies with *C. abortus*.

C. caviae

The natural host of *C. caviae* is the guinea pig. Clinical signs include conjunctivitis. *C. caviae* infection of the guinea pig is routinely used as an animal model system to study human chlamydial genital tract infections.

C. suis

C. suis is a swine pathogen and is believed to be endemic in pigs. Clinical syndromes include conjunctivitis, pneumonia, genital tract disease, and enteritis. Due to its similarity to human isolates, recent concern has arisen due to the identification of tetracycline-resistant isolates of *C. suis*.

C. avium

C. avium has been isolated from sick pigeons and psittacine birds. It is not known whether or not their natural host range is limited to these animals.

C. gallinacean

C. gallinacean can be isolated from domesticated poultry including chicken, guinea fowl and turkey. Although there is currently no evidence that this organism is pathogenic in these birds, a link between this organism and atypical pneumonia among slaughterhouse workers has been suspected.

Conclusion

Exciting advances over the last several years have revealed that *Chlamydia* species target multiple host trafficking and signaling pathways to mediate their intracellular survival and pathogenesis. Chromosome- and plasmid-encoded effector molecules are secreted into the host cell cytoplasm or the inclusion membrane through T3SS-independent and -dependent mechanisms. While some of the effectors have been shown to specifically interact with host proteins, targets of other effectors have yet to be identified. Exciting new research tools, which include transformation, inducible expression, gene targeting, mutagenesis coupled with high throughput genome sequencing, and *in vivo* imaging system for monitoring chlamydial dissemination in live animals, will help clarify the functional role of these chlamydial effectors. These tools will also aid in identification of new virulence factors and therapeutic targets, and vaccinology research.

Chlamydomorpha pneumoniae, A Pathogen Causing More Than Pneumonia

CW Stratton, Vanderbilt University School of Medicine, Nashville, TN, United States; Vanderbilt University Medical Center, Nashville, TN, United States

Recognition of *Chlamydomorpha pneumoniae* as a Human Pathogen

Chlamydomorpha (*Chlamydia*) *pneumoniae* was first recognized as a cause of human respiratory tract infections in 1986 (Grayston et al., 1986, 1990; Grayston, 1992a). In the following decade, *C. pneumoniae* became well established as a significant cause of both upper and lower respiratory tract infections, including pharyngitis, laryngitis, sinusitis, bronchitis, and pneumonia (Grayston, 1992b; Blasi et al., 2000; Burillo and Bouza, 2010). Seroepidemiology studies in most industrialized countries (Fig. 1) have demonstrated that approximately 80% of adults are infected with *C. pneumoniae* at least once in their lifetime (Grayston, 1992b; Villegas et al., 2010; Miyashita et al., 2002; Puolakkainen, 2013). Both reinfections and recurrent infections are thought to be common; pulmonary infections can become chronic and have been associated with acute exacerbations of COPD (Grayston, 1992b; Blasi et al., 1993). Importantly, the ability of *C. pneumoniae* to disseminate from the lung to distant tissue sites and then to persist in these distant host tissues for extended periods of time is a critical aspect of the pathogenesis of *C. pneumoniae* infection (Moazed et al., 1998; Gieffers et al., 2004a; Witte et al., 2011). This pathogenesis must be clearly understood in order to appreciate the potential role of *C. pneumoniae* in human disease. In particular, this ability to cause persistent infection in distant tissues is the reason that *C. pneumoniae* is a pathogen that causes more than pneumonia (Roulis et al., 2013).

Molecular Pathogenesis of Chlamydial Infections

C. pneumoniae, like other members of the *Chlamydiae* family, is an obligate intracellular human pathogen with a unique life cycle during which the microorganism exists in different phenotypes (Fig. 2). This unique life cycle is largely responsible for the molecular pathogenesis of chronic chlamydial infections in human disease (Moulder, 1991; Beatty et al., 1994; Stephens, 2003; Hogan et al., 2004; Kern et al., 2009; Elwell et al., 2016). In brief, the life cycle for *Chlamydomorpha/Chlamydia* species begins with the elementary body (EB), which is an infectious “spore-like” form with minimal metabolic activity (Omsland et al., 2014) that is able to attach to a target host cell and stimulate uptake by this host cell. For *C. pneumoniae*, airborne infectious EBs produced through coughing by infected persons appears to be the primary manner in which this infection is transmitted from one person to another (Falsey and Walsh, 1993; Theunissen et al., 1993). After attachment to and internalization within the host cell, the EB transforms into a non-infective, metabolically active form called a reticulate body (RB) (Moulder, 1991; Beatty et al., 1994; Stephens, 2003; Hogan et al., 2004; Kern et al., 2009; Elwell et al., 2016). RBs replicate by binary fission within a host-derived vacuole called an inclusion body. Energy for chlamydial replication appears primarily to be obtained from host cell ATP via ATP/ADP translocases (Schmitz-Esser et al., 2004; Trentmann et al., 2007). During the replication process, some of the RBs transform back to EBs in an asynchronous manner. Lysis of the host cell and/or exocytosis of the RBs allows the extracellular release of these infectious forms for another cycle. This replicative life cycle is characteristic of acute chlamydial infection. This biphasic nature of the acute infection with an extracellular metabolically inactive infectious form and an intracellular noninfectious metabolically active form has been recognized for some time (Roulis et al., 2013; Moulder, 1991). More recently a shift in this biphasic paradigm (Beatty et al., 1994; Stephens, 2003; Hogan et al., 2004; Kern et al., 2009; Elwell et al., 2016) has occurred with the identification of a non-replicative persistent intracellular form of *Chlamydiae*; this cryptic form is now thought to be the predominant form in chronic chlamydial infections. Moreover, the cryptic form of *C. pneumoniae* in chronic human infections appears to be adapted to the availability of iron and tryptophan as well as to the presence of interferon gamma (Falsey and Walsh, 1993; Theunissen et al., 1993; Schmitz-Esser et al., 2004).

The persistent form of *Chlamydiae* is called a cryptic body (CB) and is characterized by an altered gene expression profile (Mathews et al., 2001) as well as ultrastructural changes (Kutlin et al., 2001). Cryptic bodies do not replicate, but are metabolically active using ATP obtained from the host cell (Schmitz-Esser et al., 2004; Trentmann et al., 2007). Persistent *C. pneumoniae* organisms retain a fully functional type III secretion apparatus (Subtil et al., 2001; Mueller et al., 2014; Engel et al., 2016), which allows the continuous release of effector proteins into the host cell cytoplasm and thus ensures a *C. pneumoniae*-adjusted environment. One important aspect of a *C. pneumoniae*-adjusted environment is that *Chlamydiae* are able to gain control over the host cell apoptotic regulation, which allows a favorable environment for replication or persistence (Fisher et al., 2004; Itoh et al., 2014; Sarkar et al., 2015). Persistent *C. pneumoniae* organisms demonstrate enhanced expression of the genes required for DNA replication, but not of the genes required for cell division (Byrne et al., 2001). In particular, there is a marked upregulation of major outer membrane protein (MOMP), heat shock protein 60 (Hsp-60) and proteins with functions in DNA replication (GyrA), transcription (RpoA, PnP), translation (Rrf), glycolysis (PgK, GlgP), and type III secretion (SctN) (Molestina et al., 2002). MOMP and Hsp-60 are thought to play an important role in persistent chlamydial infections. MOMP has been shown to bias the T cell-mediated immune response towards a type 2 response rather than a

Fig. 1 Shows the age related incidence of anti-*C. pneumoniae* antibodies during the entire period. The antibody detection rate was 57%, broken down by age as follows: 6 months to 1 year old, 4%; 2–4 years old, 5%; 5–9 years old, 40%; 10–14 years old, 56%; 15–19 years old, 59%; 20–29 years old, 57%; 30–39 years old, 63%; 40–49 years old, 67%; 50–59 years old, 67%; 60–69 years old, 70%; and ≥70 years old, 71%. In subjects over 15 years old, anti-*C. pneumoniae* antibodies were present in 1331 (67.5%) of 1971 males and 1078 (60.6%) of 1777 females. There were 14 cases (0.3%) of recent *C. pneumoniae* infection among these healthy individuals, as determined by IgM.

Fig. 2 Intracellular life cycle of *Chlamydia pneumoniae*.

type 1 response; the type 2 response is less protective (Shaw et al., 2002). Heat shock proteins are important antigens expressed during chronic infection and inflammation and markedly influence and sustain anti-infectious and autoimmune responses (Zugel and Kaufmann, 1999). Chlamydial Hsp-60 is pro-inflammatory (Da Costa et al., 2004) and is known to activate macrophages (Bulut et al., 2002); *C. pneumoniae* Hsp-60 also has been shown to induce pulmonary inflammation in mice (Bulut et al., 2009) as well as inflammation in human atheroma (Kol et al., 1998). Cells persistently infected with *Chlamydiae* secrete other pro-inflammatory substances (Mannonen et al., 2011). For example, it has been noted that epithelial cells infected in vitro with *Chlamydiae* secrete large amounts of pro-inflammatory cytokines, including IL-8, GRO α , granulocyte-macrophage colony-stimulating factor, IL-1 α , and IL-6 (Rasmussen et al., 1997). Finally, persistent *C. pneumoniae* infection of vascular cells such as endothelial cells and smooth muscle cells leads to proliferative and pro-inflammatory phenotypes with endothelial dysfunction within the infected vasculature in vitro and in vivo (Gaydos, 2000; Fryer et al., 1997; Dechend et al., 1999; Coombes and Mahony, 1999; Rupp et al., 2005a).

Systemic Dissemination of *C. pneumoniae* From the Respiratory Tract

The ability of *C. pneumoniae* to cause upper and lower respiratory tract infections is well known (Grayston et al., 1986, 1990; Grayston, 1992a,b; Blasi et al., 2000; Burillo and Bouza, 2010; Blasi et al., 1993). The inflammatory response to these acute infections has been shown to be the polymorphonuclear cell (Yang et al., 1994; Pizzichini et al., 1997). The polymorphonuclear cells appear to be capable of internalizing *C. pneumoniae*, but are unable to kill this organism (Sarkar et al., 2015; Van Zandbergen et al., 2004). In fact, *C. pneumoniae* are able to extend the life span of infected polymorphonuclear cells and can replicate in these cells prior to a delayed apoptosis (Rupp et al., 2009). Moreover, these infected polymorphonuclear cells after apoptosis are taken up by macrophages; *C. pneumoniae* is then able to silently infect and propagate in these macrophages (Laskay et al., 2008). The apoptotic neutrophil as a “Trojan horse” for intracellular pathogens such as *Chlamydiae* has recently been recognized as an infection-promoting factor (Laskay et al., 2008). In a rabbit model, polymorphonuclear cells have been shown to act as a reservoir for *C. pneumoniae* (Gieffers et al., 2004a). Subsequent infection of alveolar macrophages by *C. pneumoniae* resulted in transmigration of these infected macrophages through the mucosal barrier to the lymphatic system and the systemic circulation of the rabbit. In addition, infected peripheral blood monocytes in the rabbit were shown to transmit chlamydial infection to the vascular wall. Systemic dissemination of *C. pneumoniae* by macrophages in the murine model also has been described (Moazed et al., 1998; Yang et al., 1995). Evidence for systemic dissemination in the human is provided by a number of studies investigating the prevalence of *C. pneumoniae* in white blood cells collected from healthy blood donors (Boman et al., 1998; Kaul et al., 2000; Bodetti and Timms, 2000; Haranaga et al., 2001; Rassu et al., 2001; Cirino et al., 2006). In particular, one study has demonstrated a *Chlamydiae* carriage rate of 24.6% within white blood cells (WBCs) from the normal blood donor population (Cirino et al., 2006). *Chlamydia* organisms were not only present within the mononuclear/macrophage cells as previously described (Boman et al., 1998; Kaul et al., 2000; Bodetti and Timms, 2000; Haranaga et al., 2001; Rassu et al., 2001; Cirino et al., 2006), but were also present within neutrophils and eosinophil/basophil cells (Cirino et al., 2006). Moreover, this study also demonstrated that the *Chlamydia* organisms in lysates of these peripheral WBCs were infectious and could be cultured (Cirino et al., 2006). This strongly suggests that such carriage of *Chlamydia* organisms in peripheral WBCs could lead to infection of other tissues. Such infection by *C. pneumoniae* has been described in the bone marrow (Nebe et al., 2005) as well as on a heart valve (Gdoura et al., 2002). Clearly, *Chlamydiae* can disseminate and cause infection in distant tissues of humans. Phylogenetic analysis of *C. pneumoniae* isolates from cardiovascular tissues and from brain have been compared to published whole genomes from respiratory isolates (Roulis et al., 2015); fine-detailed analysis of these new *C. pneumoniae* sequences have revealed several genetically variable loci suggesting that minor genetic differences may contribute to adaptation of particular strains in human disease.

Evolving Role of *C. pneumoniae* in Human Disease

The role of *C. pneumoniae* in human disease is evolving. *C. pneumoniae* is known to infect a large variety of human cells including alveolar epithelial cells, macrophages, monocytes, dendritic cells, B-cell, T-cells, polymorphonuclear cells, vascular endothelial cells, smooth muscle cells, fibroblasts, neuronal glia cells, and neuronal ependymal cells (Moulder, 1991; Beatty et al., 1994; Stephens, 2003; Hogan et al., 2004; Kern et al., 2009; Elwell et al., 2016). *C. pneumoniae* is known to be present in an infectious elementary body form within peripheral WBCs in up to 50% of humans (Boman et al., 1998; Kaul et al., 2000; Bodetti and Timms, 2000; Haranaga et al., 2001; Rassu et al., 2001; Cirino et al., 2006). *C. pneumoniae* also is able to cause chronic intracellular infections for which the hallmark is a chronic inflammatory response due to secretion of heat shock proteins and proinflammatory cytokines/chemokines (Moulder, 1991; Beatty et al., 1994; Stephens, 2003; Hogan et al., 2004; Kern et al., 2009; Elwell et al., 2016). Therefore, an important aspect for ongoing investigations of the pathogenesis of *C. pneumoniae* is which tissues are involved/infected, what are the specific roles of the various chlamydial forms (EB, RB, and CB), what are the clinical manifestations of such a chronic infection, and what is the evidence for causation?

To date, there have been a number of important associations of *C. pneumoniae* with chronic human diseases for which the exact role of *Chlamydiae* is still being elucidated (Choroszy-Krol et al., 2014). Four examples of such associations will be briefly reviewed in the following sections. The potential current and future roles of antimicrobial therapy for chronic chlamydial infections also will be discussed.

Association of *C. pneumoniae* With Asthma

An important site-specific pathogenesis association for chlamydial respiratory tract infections is asthma (Hahn et al., 1991; Hahn, 1998). It has been estimated that *C. pneumoniae* is responsible for approximately 20% of lower respiratory tract infections (Grayston, 1992a,b; Blasi et al., 2000; Burillo and Bouza, 2010; Villegas et al., 2010; Puolakkainen, 2013; Kauppinen and Saikku, 1995). *C. pneumoniae* respiratory tract infection may be an important factor in the pathogenesis and course of bronchial asthma in both adults (Hahn et al., 1991; Endo et al., 2017) and children (Emre et al., 1994; Webley et al., 2005; Asner et al., 2014; Iramain et al., 2016). Bronchial smooth muscle cells are potential host cells for *C. pneumoniae* during acute or chronic chlamydial respiratory tract infections; chlamydial infection of human smooth muscle cells has been shown to elicit basic fibroblast growth factor and interleukin 6 (Rodel et al., 2000). This type of bronchial response is thought to contribute to airway wall remodeling in a subset of

patients with *Chlamydia*-associated chronic asthma (Rodel et al., 2000; Hahn and Peeling, 2008; Metz and Kraft, 2010). Moreover, asthma and reactive airway disease is almost always associated with some kind of IgE-related reaction (Burrows et al., 1989). Therefore, *C. pneumoniae*-specific IgE has been investigated as a potential factor in the pathogenesis of reactive airway disease associated with chlamydial infections of the respiratory tract. Anti-*C. pneumoniae* IgE has been found in both children (Emre et al., 1995; Patel et al., 2012) and adults (Hahn et al., 2012) with asthma with *C. pneumoniae*-specific IgE being associated with the severity of asthma in both groups (Patel et al., 2012; Hahn et al., 2012). Finally, a number of studies have noted that antimicrobial agents such as macrolides and doxycycline are beneficial as adjunct therapy for asthma (Johnston et al., 2006; Dzhindzhikhashvili et al., 2013; Gibson et al., 2017), raising the valid question as to the role of such antimicrobial therapy on asthma caused by chronic *C. pneumoniae* lung infection (Hahn and Webley, 2016; Webley and Hahn, 2017).

Association of *C. pneumoniae* With Cardiovascular Disease

Another important association is that first described by Saikku involving the serologic association of *C. pneumoniae* with atherosclerosis and cardiovascular disease (Saikku, 1993, 1999, 2000). In the subsequent two decades, there have been a large number of studies and reports in the medical literature suggesting that chlamydial infection of vascular tissues may contribute to the pathogenesis of atherosclerosis (Saikku, 1993, 1999, 2000; Shor and Phillips, 2000; Palikhe et al., 2009; Fazio et al., 2009; Sessa et al., 2009; Player et al., 2014; Pigarevskii et al., 2015; Assar et al., 2015; Filardo et al., 2015; Yazouli et al., 2017); these include seroepidemiological and pathological studies as well as in vivo and in vitro studies. There are a number of ways that *C. pneumoniae* might play a role in atherosclerosis. Infectious elementary bodies circulating in the blood stream (Cirino et al., 2006) might directly infect endothelial cells and thus initiate the process of atherosclerosis (Kaukoranta-Tolvanen et al., 1994; Kreutmayer et al., 2013; Sun et al., 2014). Infection of endothelial cells could lead to infection of smooth muscle cells (Rodel et al., 2000; Gaydos et al., 1996). *C. pneumoniae* could also infect monocytes/macrophages before (Rupp et al., 2009) or after (Kalayoglu and Byrne, 1998; Mei et al., 2009) the monocytes/macrophages migrate to the infected endothelial cells in vascular tissue; *C. pneumoniae*-infected monocytes/macrophages in vascular tissue would result in foam cells (Kalayoglu and Byrne, 1998; Mei et al., 2009). Macrophage foam cell formation is the hallmark of early atherosclerosis (Kalayoglu and Byrne, 1998; Mei et al., 2009; Yu et al., 2013). Moreover, foam cells have been histologically implicated in the pathogenesis of acute myocardial infarction (Horie et al., 1978). *C. pneumoniae* has been detected in 32 of 51 (63%) coronary primary lesions of symptomatic patients; a highly significant prevalence of these lesions were associated with acute coronary syndrome suggesting a pathological role of *C. pneumoniae* in coronary plaque rupture (Baauriedel et al., 1999). Although these epidemiologic, laboratory, animal, and clinical studies have clearly established an association of *C. pneumoniae* with atherosclerosis, the question of whether this organism plays a contributory role versus a causal role or is a simple symbiotic passenger remains controversial (Mahoney and Coombes, 2001; Baker et al., 2009; Honarmand, 2013). This controversy, in part, is due to the lack of response with antimicrobial intervention in large randomized controlled clinical trials (Muhlestein, 2003; O'Conner et al., 2003; Grayston et al., 2005). Interestingly, in one large trial (WIZARD), stable post-myocardial infarct patients were randomized to receive a 3-month course of azithromycin or placebo; those receiving the single antibiotic demonstrated a significant reduction in death and myocardial infarction by 6 months, but this effect was not sustained (O'Conner et al., 2003). This lack of efficacy may be related to the fact that *C. pneumoniae* causes persistent infection that is refractory to antimicrobial therapy (Campbell and Rosenfeld, 2014). Additional studies are needed (Campbell and Rosenfeld, 2014, 2015).

Association of *C. pneumoniae* With Neurodegenerative Diseases

C. pneumoniae also has been associated with neurodegenerative diseases (Boelen et al., 2009; Contini et al., 2010) such as Alzheimer's disease (Stallings, 2008) and multiple sclerosis (Fainardi et al., 2008). Each of these two associations will be reviewed. The demonstration of *C. pneumoniae* by histopathological, molecular, and culture techniques in late-onset Alzheimer's disease dementia was first reported in 1998 by Balin and colleagues. These investigators then utilized electron and immunoelectron microscopic techniques (EM, IEM respectively) in order to characterize the ultrastructure of *C. pneumoniae* in Alzheimer's disease (AD) brain tissue (Arking et al., 1999). The AD brain tissue examined demonstrated both intracellular reticulate bodies and extracellular elementary bodies, with some of the intracellular organisms undergoing binary fission. Moreover, some AD brain tissue demonstrated atypical forms exhibiting a less distinct cell membrane and a granular center containing possible nucleic acid dense bodies. These atypical forms may represent the cryptic phase of *C. pneumoniae* (Hogan et al., 2004; Kern et al., 2009; Elwell et al., 2016; Arking et al., 1999). Because other investigators were unable to confirm the presence of *C. pneumoniae* in AD brain tissue using either PCR or immunohistochemistry methods (Gieffers et al., 2000; Ring and Lyons, 2000), Balin et al. utilized immunohistochemistry with a battery of commercially available anti-*C. pneumoniae* antibodies and confirmed that *C. pneumoniae* was present in areas typically associated with AD neuropathy (Hammond et al., 2010). Gerard et al. utilized PCR targeting the Cpn1046 and Cpn0695 genes and confirmed the presence of *C. pneumoniae* in an additional 20/27 cohort of patients with late-onset Alzheimer's disease (Gerard et al., 2006). In addition, *C. pneumoniae* has been cultured from AD brain samples from different geographic regions of North America (Dreses-Werringloer et al., 2009). Finally, Balin et al. have used a murine model to demonstrate that intranasal infection with *C. pneumoniae* induces Alzheimer-like amyloid plaques in the brains of BALB/c mice (Little et al., 2004, 2014). Another possibility for other investigators not being able to confirm the presence of *C. pneumoniae* in AD

brain tissue is that other pathogens might also be triggers for Alzheimer's disease (Maheshwari and Eslick, 2015). In particular, spirochetes also are associated with Alzheimer's disease (Maheshwari and Eslick, 2015; Miklossy et al., 2004; Miklossy, 2011, 2015; Allen, 2016). In summary, the evidence strongly suggests that *C. pneumoniae* is one of several bacteria that play an important role in the neuropathogenesis of Alzheimer's disease (Maheshwari and Eslick, 2015; Balin et al., 2008). Moreover, unlike single agent antimicrobial therapy for atherosclerosis, combination antimicrobial therapy with doxycycline and rifampin for 3 months in a randomized controlled trial demonstrated significantly less decline as measured by the Standardized Alzheimer's Disease Assessment Scale cognitive subscale (Loeb et al., 2004).

Another neurodegenerative disease in which *C. pneumoniae* may play a role is multiple sclerosis (Contini et al., 2010; Stratton and Wheldon, 2006; Stratton, 2016). *C. pneumoniae* is known to infect neutrophils and inhibit apoptosis of these cells (Sarkar et al., 2015; Van Zandbergen et al., 2004). This allows *Chlamydia*-infected neutrophils to serve as transport vehicles that can serve as "Trojan horses" and spread to macrophages as well as to distant sites such as the brain (Rupp et al., 2009; Laskay et al., 2008; Gieffers et al., 2004a). *Chlamydia*-infected macrophages/monocytes are able to infect vascular cells, including those in the brain (Rupp et al., 2005b). In order to understand how *Chlamydia*-infected neutrophils and/or macrophages/monocytes might pass through the blood brain barrier and directly infect the brain, a review of the choroid plexus and the circumventricular organs is useful (Wolburgh and Paulus, 2010; Duvernoy and Risold, 2007). The choroid plexus is a complex epithelial–endothelial vascular interface within the ventricular system of the vertebrate brain (Wolburgh and Paulus, 2010). It is comprised of epithelial cells, fenestrated blood vessels, and stroma; the choroid plexus is primarily involved in the production of cerebrospinal fluid (CSF). The circumventricular organs are structures lining the cavity of the third and fourth ventricle and possess a vascular architecture in which their capillaries have a wall devoid of blood-brain barrier (Duvernoy and Risold, 2007). Indeed, the hallmarks of the circumventricular organs are fenestrated capillaries with high permeability that are located in the third and fourth ventricles. This unique arrangement permits direct exchange between the blood and the nervous tissue located near these organs. The circumventricular organs are thought to be a possible entry site for circulating white blood cells into the CSF (Schulz and Engelhardt, 2005). The fenestrated capillaries of the circumventricular organs are regulated by angiogenesis, which involves the active proliferation of endothelial cells (Miyata, 2015). Such endothelial cells could be easily infected by transendothelial migration of *C. pneumoniae* from infected peripheral blood mononuclear cells as has been demonstrated in an experimental transendothelial migration model (Rupp et al., 2005b). Evidence that this can occur is seen in a report of chlamydial infection of ependymal cells in the ventricular tissues of some patients with multiple sclerosis (Sriram et al., 2005a). These investigators suggest that the circumventricular organs may allow entry of *C. pneumoniae*-infected mononuclear cells into the CNS. Infection of ventricular ependymal cells by *C. pneumoniae* could then lead to cytokine-mediated damage to brain tissue surrounding these ventricles. Moreover, infection of ventricular ependymal cells by *C. pneumoniae* would explain the visualization by electron microscopy of chlamydial elementary bodies in the CSF of MS patients (Sriram et al., 2005a). Such ventricular infection by *Chlamydia* would also explain the observations that affinity-driven immunoblot studies have demonstrated reactivity of oligoclonal bands in CSF from MS patients against elementary body antigens of *C. pneumoniae* (Yao et al., 2001; Fainardi et al., 2009). Finally, ventricular infection by *C. pneumoniae* would explain the presence of chlamydial DNA and mRNA transcripts in CSF from some patients with MS (Dong-Si et al., 2004; Contini et al., 2008a).

C. pneumoniae is known to produce large amounts of heat shock protein 60 (HSP 60) during chronic, persistent infections (Zugel and Kaufmann, 1999; Da Costa et al., 2004; Bulut et al., 2002, 2009; Kol et al., 1998); this HSP 60 is thought to play an important role in the pathogenesis of chronic chlamydial infections (Stephens, 2003). Heat shock protein 60 is an evolutionarily conserved protein in both eukaryotes and prokaryotes that is recognized as potent activator of the innate immune system and is capable of inducing the production of pro-inflammatory cytokines by the monocyte–macrophage system (Tsan and Gao, 2004b; Habich and Burkart, 2007; Henderson et al., 2013). Importantly, human mitochondrial HSP 60 has been proposed as a danger signal of stressed or damaged cells (Miyata, 2015). Both chlamydial HSP 60 and human HSP 60 contribute to inflammation in human atheroma and are able to induce inflammation to levels induced by *Escherichia coli* lipopolysaccharide (Kol et al., 1998). Infection of ventricular ependymal cells by *C. pneumoniae* or other pathogens could serve as a focus of HSP 60, which in turn would stress and/or damage neurons and oligodendrocytes resulting in neuronal cell death, axonal injury, loss of oligodendrocytes, and demyelination (Rosenberger et al., 2015). Such HSP 60 mediated neurodegeneration and demyelination in the CNS has been described in a murine model in which intrathecal HSP 60 is injected (Lehnardt et al., 2008). The fact that neurodegeneration and demyelination in the CNS involves TLR4 and MyD88 confirms that this molecular pathway is able to the release of endogenous TLR ligands from injured CNS cells and is a common process in many different types of brain injury. Indeed, once there is a brain injury involving release of HSP 60 has occurred, a vicious cycle can occur due to the activation of microglia, the resident CNS monocyte. Such a cycle involving release of HSP 60 from injured CNS tissue with activation of toll-like receptor 4 has been shown to mediate neurodegeneration in the CNS of mice (Prabhakar et al., 1994) and has been implicated in multiple sclerosis and myalgic encephalomyelitis (Elfaitouri et al., 2013; Amor et al., 2014).

There is clearly a subset of patients with multiple sclerosis in which an association between culture and/or PCR positivity for *C. pneumoniae* in CSF and disease activity has been noted (Sriram et al., 1999; Layh-Schmitt et al., 2000; Contini et al., 2004; Tang et al., 2009). Moreover, intrathecal production of anti-*C. pneumoniae* high-affinity IgG predominated in progressive forms of multiple sclerosis (Yao et al., 2001), and oligoclonal bands include antibodies that react with antigens from *C. pneumoniae* (Fainardi et al., 2009). Metabolically active *C. pneumoniae* has been identified in the CSF of patients with progressive forms of multiple sclerosis (Dong-Si et al., 2004; Contini et al., 2008a). Finally, *C. pneumoniae* has been identified in CSF and/or brain tissue of multiple sclerosis patients using immunohistochemical, molecular, and ultrastructural methods (Sriram et al., 2005a). Finally, the presence of *Chlamydia*-like organism DNA has been reported in several patients with relapsing-remitting MS

(Contini et al., 2008b). Although antimicrobial treatment for chlamydial infection in patients with multiple sclerosis has not been well studied, long-term treatment with a single agent, roxithromycin, was not effective (Woessner et al., 2008) whereas combination therapy with azithromycin and rifampin for 6 months showed a significant reduction in brain parenchymal fraction loss despite the lack of statistical power due to the small number of subjects (Sriram et al., 2005b). A prolonged antimicrobial regimen consisting of combination therapy has also been shown to improve the extra-cranial circulation in patients with MS (Thibault et al., 2017). This beneficial effect was statistically significant in patients with positive serology for *C. pneumoniae*.

Association of *C. pneumoniae* With Inflammatory Arthritis

Chlamydia species, including both *Chlamydia trachomatis* and *C. pneumoniae*, have been associated with a chronic inflammatory arthritis following acute infections at distant sites (Carter and Hudson, 2017). In reactive arthritis induced by either of these two *Chlamydia* species, organisms are viable and metabolically active in the synovium where they exist in a persistent state of infection (Gerard et al., 2000, 2013). Of note is that mRNA from the chlamydial hsp60 gene has been detected in synovial fluid in patients with reactive arthritis. HSP 60 is a well-recognized pro-inflammatory factor secreted by both *C. pneumoniae* (Zugel and Kaufmann, 1999; Da Costa et al., 2004; Bulut et al., 2002, 2009; Kol et al., 1998) and *C. trachomatis* (Cohen et al., 2005). Moreover, HSP 60 is typically secreted by the cryptic forms of *Chlamydia* species (Beatty et al., 1994; Stephens, 2003; Hogan et al., 2004; Kern et al., 2009; Elwell et al., 2016). The term “reactive arthritis” has been used to describe the association of *Chlamydia* species with this inflammatory process involving joints (Carter and Hudson, 2017; Gerard et al., 2000, 2009, 2013; Cohen et al., 2005; Villareal et al., 2002; Carter and Hudson, 2010) because micro-organisms have never been cultured from synovial effusions in early disease (Taylor-Robinson and Keat, 2015). However, reactive arthritis is generally a form of seronegative spondyloarthritis associated with migratory oligoarthritis and extra-articular symptoms that typically follow a gastrointestinal infection or urogenital infection (Selmi and Gershwin, 2014). The fact that there are metabolically active *Chlamydiae* in the joints strongly suggests that the role of these *Chlamydiae* is causal; the causal nature is further strengthened by the response to prolonged antimicrobial therapy (Zeidler and Hudson, 2016). Prolonged antimicrobial therapy with a single antichlamydial agent such as azithromycin or doxycycline has been shown to be ineffective in reactive arthritis (Kvien et al., 2004; Carter et al., 2004) in contrast to combination therapy with either azithromycin or doxycycline combined with rifampin, which have demonstrated a therapeutic benefit for the treatment of reactive arthritis (Carter et al., 2004, 2010; Rihl et al., 2010).

Clearly, the role of *C. pneumoniae* in chronic human diseases is evolving. The four examples described above may be only the first of many instances where persistent infection with *C. pneumoniae* plays a role in chronic human diseases. Antichlamydial therapy may ultimately be beneficial in such chronic human diseases.

The Future of Antimicrobial Therapy for Chronic Chlamydial Infections

Persistent pulmonary infections with *C. pneumoniae* are a recognized complication of acute respiratory illness with this pathogen (Grayston et al., 1990; Grayston, 1992a,b; Blasi et al., 1993, 2000; Burillo and Bouza, 2010), and this microorganism has proven difficult to eradicate from the respiratory tract with a single agent using currently available antibiotics (Hammerschlag et al., 1992; Branden et al., 2004). Initial attempts to eradicate *C. pneumoniae* using a single agent in patients with cardiovascular disease have all failed (Muhlestein, 2003; O’Conner et al., 2003; Grayston et al., 2005). These observations can be explained, in part, by the fact that the persistent phase of chlamydial infection is relatively refractory to antimicrobial therapy (Gieffers et al., 2001; Yamaguchi et al., 2003). Moreover, first-line antichlamydial agents in subinhibitory concentrations have been shown to induce chlamydial persistence (Gieffers et al., 2004b).

Although clinical data is limited at this time, combination therapy with a regimen that includes a rifampin (Siewert et al., 2005) for a prolonged period of time does appear to be more effective against chronic chlamydial infections than does a single agent. Treating chronic chlamydial infections seems to be similar to treating tuberculosis in that prolonged therapy (i.e., months) with a combination of antichlamydial agents appears to be effective whereas shorter courses (i.e., weeks) with a single antichlamydial agent are not. Optimal therapy for chronic chlamydial infections is apt to required combinations of antimicrobial agents that ideally should be selected on their activity against in vitro persistent chlamydial infections. However, susceptibility testing of *Chlamydia* species is difficult since this pathogen is an obligate intracellular microorganism and not amenable to standard antimicrobial susceptibility testing methods.

Introduction

The phylum *Chloroflexi* is a deeply branching phylum of the *Bacteria*, which harbors extensive intraphylum diversity and is found in a wide range of aquatic and terrestrial environments. Before the name *Chloroflexi* was first proposed in 2001, members of this phylum were referred to as 'Green non-sulfur bacteria'. The phylum was named after the genus *Chloroflexus*, and its type species, *Chloroflexus aurantiacus*, a filamentous anoxygenic phototrophic bacterium that was first found in hot springs and described by Pierson and Castenholz in 1974. As a 'green' phototrophic bacterium that lived in 'non-sulphidic' environments, it represented the group of 'green non-sulfur bacteria' (GNSB), which now is termed 'filamentous anoxygenic phototrophs' (FAP), a term used specifically for phototrophic members of the *Chloroflexi*. Members of this phylum have first been described in microbial mats associated with extreme conditions such as thermal and hypersaline environments. Subsequently, *Chloroflexi* have further been detected in a variety of mesophilic freshwater and marine environments, including wastewater treatment plants and even are part of the human microbiome.

Taxonomy and Phylogeny

Formerly, the phylum *Chloroflexi* had been divided into four major subphylum (class)-level taxa, i.e., 'subphyla I, II, III, and IV', which have been re-classified into at present (2018) eight classes containing isolated and described representatives: the *Anaerolineae*, *Ardenticatenia*, *Caldilineae*, *Chloroflexia*, *Dehalococcoidia*, *Ktedonobacteria*, *Thermoflexia* and *Thermomicrobia*. In addition, ribosomal sequences recovered from a variety of environments indicate the presence of many more, still uncultured, class-level groups within the *Chloroflexi*; approx. 25–30 total classes are estimated to exist in this phylum (Fig. 1). In this article we will give an overview of the known members of the phylum *Chloroflexi*, regardless of their official standing in nomenclature. Published taxonomic names are included also for not 'validly' described species and uncultured '*Candidatus*' taxa. (Suppl. Table 1).

The class *Anaerolineae* (Suppl. Fig. 1(A)), together with the *Caldilineae*, used to constitute the '*Chloroflexi* subphylum I'. The class contains a single family, *Anaerolineaceae*, which is composed of ten genera with isolated representatives, *Anaerolinea*, *Bellilinea*, *Flexilinea*, *Leptolinea*, *Levilinea*, *Longilinea*, *Ornatilinea*, *Pelolinea*, *Thermanaerotherix* and *Thermomarinilinea*; as well as many additional uncultured clades, including "*Candidatus* Brevefilum" and the freshwater clade CL500–11. All isolated members belonging to these families possess multicellular filamentous morphology, and are strictly anaerobic chemotrophic organisms isolated from anaerobic digesters, hot springs or submarine sediment. In contrast to the members of the *Chloroflexia* (see below) they do not possess gliding motility.

The class *Ardenticatenia* was proposed based on a single species, the ferric ion- and nitrate-reducer, *Ardenticatena maritime*, isolated from a costal hydrothermal field. The species forms thin multicellular filaments and can grow at temperatures of up to 75°C. At the moment, the class contains only one family, *Ardenticatenaceae*, and one order, *Ardenticatenales*. However, ribosomal genes obtained in cultivation-independent studies from a variety of different environments indicate the presence of at least two more family level groups, one including the proposed taxon "*Candidatus* Promineofilum breve", detected in activated sludge flocs and formerly known as "Eikelboom morphotype 0092".

The class *Caldilineae* contains a single described family, *Caldilineaceae*, which consist of two genera, *Caldilinea* and *Litorilinea*. Species belonging to these genera are facultative aerobic or strictly anaerobic filamentous organisms found in hot springs or hot aquifers. Additional uncultured clades, possibly representing several genera in a second family, one including "*Candidatus* Defluviifilum", are indicated by ribosomal gene sequences.

The class *Chloroflexia* (Suppl. Fig. 1(B)) (sometimes also called *Chloroflexi*), formerly known as 'subphylum III', contains the first known members of this phylum, and three orders, *Chloroflexales*, *Herpetosiphonales* and *Kallotenuales*. Members of this class mostly possess filamentous growth morphology, and show photoheterotrophic and/or chemoheterotrophic growth under mesophilic or moderately thermophilic conditions. All isolated and described filamentous, anoxygenic phototrophic bacteria (FAP) are found in this class. Similar to the phylum, the class was named after the first isolated representative, *Chloroflexus aurantiacus*. All isolated and described phototrophic members are found in the order *Chloroflexales* which can be divided into three families, *Chloroflexaceae*, *Roseiflexaceae* and *Oscillochloridaceae*. The former two families are composed of thermophilic FAPs isolated from terrestrial hot springs, while the *Oscillochloridaceae* contains phototrophic mesophilic freshwater species. Although phototrophy in *Chloroflexi* isolates is limited to this class, metagenomic studies indicate the existence of phototrophic members also in other classes (see below).

The family *Chloroflexaceae* contains *Chloroflexus* (*Cfl.*) as its only validly described genus, which presently consists of three validly described species, i.e., *Cfl. aurantiacus* as the type species, *Cfl. aggregans* and *Cfl. islandicus*. The existence of additional undescribed species in this genus has been indicated by isolated strains and ribosomal gene sequences from uncultured members obtained from

Fig. 1 Phylogenetic tree showing cultured and uncultured classes in the *Chloroflexi*. The tree displays the 16S rRNA gene sequence based SILVA SSU Ref_NR_99 backbone tree (SILVA Release 132, released on 13.12.2017) with some additional sequences and names added. Clades displayed in red contain isolated representatives, while black clades contain only sequences from uncultured microbes. Ca. = Candidatus; Sp = Subphylum. Available at: <https://www.arb-silva.de/download/arb-files/>.

different hot spring environments. All isolates from this genus are 'green' thermophilic anoxygenic phototrophic organisms able to grow at 55°C, which contain the green bacteriochlorophyll (BChl) *c* as their major photosynthetic pigment, specifically found in light harvesting units called "chlorosomes", as well as BChl *a* in their photosynthetic reaction centers. Further, mesophilic FAP isolated from mesophilic alkaline environments are included in this family as members of the genus "*Candidatus Chloroploca*". "*Candidatus Chloroploca asiatica*" members are characterized by immotile, short trichomes which are surrounded by a mucous sheath, and a high sulfide tolerance (up to 8 mM). They resemble green FAP; contain BChls *a* and *c*, and are capable of photoautotrophic growth using sulfide as electron donor.

The family *Oscillochloridaceae*, containing the two genera *Chloronema* and *Oscillochloris*, harbors filamentous anoxygenic phototrophic bacteria from non-thermophilic environments. *Chloronema giganteum*, the only described species of the genus *Chloronema*, is a mesophilic FAP which contains BChl *d* as well as *c* and was isolated from a freshwater lake. *Oscillochloris chrysea* and *O. trichoides* were found by Russian researchers in mesophilic fresh- and brackish-water environments. The families *Chloroflexaceae* and *Oscillochloridaceae* are combined in the suborder *Chloroflexineae*.

Other green FAP related to *Chloroflexus* spp. have been detected in marine and hypersaline environments, and termed 'Marine *Chloroflexus*-like organisms', or MCLOs. One representative of this group, "*Candidatus Chlorothrix halophila*", has been grown in the laboratory in a mixed enrichment culture. These bacteria share the characteristic cell morphology of all FAP i.e., an unbranched multicellular filamentous shape, and show gliding motility, a type of flagella-independent motility described in more detail below.

The family *Roseiflexaceae*, the only family of the suborder *Roseiflexinae*, contains the so called 'red FAP', in two genera with described representatives with a single described species each, *Roseiflexus* and *Heliothrix*, as well as the so far not validly described "*Kouleothrix aurantiaca*". Red FAP owe their name to their orange-red color, which is due to the lack of BChl *c*-containing chlorosomes which give the green FAP of the *Chloroflexineae* their characteristic green color. *Heliothrix oregonensis* and *Roseiflexus castenholzii* were isolated from hot springs in USA and Japan, respectively. A strain of a second but so far undescribed species of *Roseiflexus* has been isolated from hot springs in Yellowstone National Park (USA). "*Kouleothrix aurantiaca*" is a member of the 'Eikelboom morphotype 1851' and was isolated from activated sludge in an industrial wastewater treatment facility. Phototrophy has not been observed in the isolate, but has been suggested by the presence of all genes required for anoxygenic phototrophy in its genome. The presence of several more so far uncultured genera is indicated by ribosomal gene sequences obtained from a variety of habitats.

The other two orders of the class *Chloroflexia*, the *Herpetosiphonales* and *Kallotenuales* include one family each, the *Herpetosiphonaceae* and *Kallotenueaceae*. Unlike the members of the *Chloroflexales*, the members in these families are aerobic chemotrophic bacteria, which use organic compounds for growth but lack the ability to use light energy. However, similarly to the FAP they show filamentous morphology and gliding motility allowing them to move over solid surfaces. The four described species of the *Herpetosiphonales* were isolated from soil, freshwater and hot spring environments, while *Kallotenue papyrolyticum* represents a thermophilic and cellulolytic bacterium isolated from Great Boiling Spring, NV (USA). The species of the genus *Herpetosiphon* are specifically interesting as they have been described to feed on other bacteria and destroy whole colonies of several species of microorganisms (see below).

The class *Dehalococcidia*, previously known as '*Dehalococcoides*' or '*Chloroflexi* subphylum II' has only recently (in 2013) been proposed as a class. It possesses only one family, *Dehalococcoidaceae*, containing two described genera, *Dehalococcoides* and *Dehalogenimonas*. Unlike many other members in this phylum, their cells are not filamentous but disc-shaped coccoid. Dehalogenation of chlorinated alkanes is a remarkable feature of all isolated members of the class.

The uncultured 'SAR202 clade', formerly known as '*Chloroflexi* subphylum IV', is most closely related to the isolated members of the class *Dehalococcidia*; in some phylogenetic trees, such as the SILVA Tree Viewer (see Section '[Relevant Websites](#)'), the clade is considered to be included in this class. It was first obtained from the Sargasso Sea and prevalent in deep oceans environments, especially in the marine subsurface (see Section [Ecology](#)).

The class *Ktedonobacteria* consists of three families, *Ktedonobacteriaceae*, *Thermosporotrichaceae* and *Thermogemmatissporaceae*, containing the genera, *Ktedobacter*, *Thermosporothrix*, and *Thermogemmatisspora*, respectively. Members of the families *Thermosporotrichaceae* and *Thermogemmatissporaceae* are thermophilic bacteria, while *Ktedobacter racemifer* represents a mesophilic aerobic heterotroph. All members were isolated from soil samples, *Thermogemmatisspora* spp. from fallen leaves within such. The species in this class share the unusual characteristic of forming branched vegetative or aerial mycelia as well as spores similar to members of the phylum *Actinobacteria*.

The class *Thermoflexia* containing the single family *Thermoflexaceae* was named after a filamentous chemotroph, *Thermoflexus hugenholtzii*, isolated from a hot spring. The species is a thermophilic, chemotrophic, microaerobe able to grow at up to 8% O₂ with the optimal growth at 1%.

The class *Thermomicrobia* is composed of thermophilic chemoheterotrophic aerobes with irregular rod morphology. The class involves two families, *Thermomicrobiaceae* and *Sphaerobacteraceae* with the genera *Thermomicrobium*, *Sphaerobacter* and *Nitrolancetus*. *N. hollandicus*, the type species of the genus *Nitrolancetus*, is a chemolithoautotrophic nitrite oxidizer, growing on nitrite and CO₂; and is the first (and to date only) nitrifying member of the phylum *Chloroflexi*.

Thermobaculum terrenum is a thermophilic, strictly aerobic, non-phototrophic member of the *Chloroflexi*, most closely related to the class *Thermomicrobia*. It was isolated from thermal soils, and displays rod-shaped cell morphology. It stains gram-positive, which is unusual for this phylum. Its taxonomic affiliation has not been specified, but based on ribosomal genes it can be suggested to represent a novel class in this phylum.

Metagenome based analysis of hot spring microbial mats indicate the presence of novel phototrophs in this phylum, which are not affiliated with the *Chloroflexia*. The uncultured class “*Candidatus Thermofonsia*” has been proposed to contain some of these phototrophs. Also the novel phototroph, “*Candidatus Roseilinea gracile*”, which was detected in a hot spring microbial mats in Yellowstone National Park (USA), was affiliated with this class based on RpoB genes. However, based on its 16S rRNA gene sequences and the SILVA backbone tree, it most likely represents the uncultured class ‘RBG-13-54-9’. “*Candidatus Roseilinea gracile*” has been suggested to grow photoheterotrophically, contains thin short filamentous cell morphology, and the ability to produce photosynthetic pigments under aerobic conditions. They do not contain the characteristic green BChl *c* or chlorosomes, and thus resemble the red FAP such as *Roseiflexus castenholzii*. These findings point at a greater phototrophic diversity within the phylum *Chloroflexi* than previously recognized, and indicates horizontal gene transfer of photosynthesis genes within the phylum.

Physiology, Metabolism and Motility

A diverse range of metabolisms and physiologies are found in the phylum *Chloroflexi* (Table 1, Fig. 2). Anoxygenic phototrophy, obligate aerobic/anaerobic heterotrophy, organohalide-respiration and CO-oxidation have been observed. The phylum contains filamentous, coccoid and rod-shaped cell morphologies, thermophilic as well as mesophilic members, halophilic organisms, and even predatory microbes.

Most isolated members in the majority of the classes of this phylum share a multicellular filamentous morphology: all described species belonging to the classes *Anaerolineae*, *Ardenticatenia*, *Caldilineae*, *Chloroflexia*, *Ktedonobacteria* and *Thermoflexia* show multicellular filamentous morphology without exception (Table 1, Fig. 2(A),(B),(F) and (G)). The filamentous members of the *Chloroflexia* are capable of gliding over solid surfaces (see below). Only members of the classes *Dehalococcoidia* and *Thermomicrobia* do not show filamentous growth, but are represented by disc-shaped, coccoid, or rod-shaped cells (Table 1, Fig. 2(C–E)). Members of the class *Ktedonobacteria* are further characterized by a special type of filamentous growth, forming branched mycelia similar to *Actinomycetes*.

The first metabolism known to occur in this phylum was anoxygenic phototrophic growth as found in the members of the *Chloroflexaceae* (Table 1). The filamentous phototrophs use light energy in a chlorophyll-dependent photochemical process to generate chemical energy in form of ATP and reduction equivalents in form of NAD(P)H. As they cannot split water, they do not produce oxygen (hence the name ‘anoxygenic’ photosynthesis). Electron sources used are reduced sulfur compounds, such as (poly) sulfide, thiosulfate, small organic molecules, or molecular hydrogen. Phototrophy has been indicated to be present also in other *Chloroflexi* classes based on cultivation-independent genomic studies. However, as of now, all other isolated members of this phylum only grow chemotrophically. Almost all phototrophic members of the *Chloroflexi* have been shown to grow photoheterotrophically assimilating organic carbon compounds. Although many contain genes for known carbon fixation pathways, photoautotrophic growth has been demonstrated only in a few isolates (see below).

Almost all phototrophic members have also been shown to grow chemotrophically under aerobic dark conditions. Further, anaerobic chemoheterotrophic growth is found in the *Anaerolineae*, *Ardenticatenia*, and *Dehalococcoidia*, while members of the

Table 1 Differential characteristics of the eight described classes in the phylum *Chloroflexi*

Characteristics	Chloroflexia	Anaerolineae	Ardenticatenia	Caldilineae	Dehalococcoidia	Ktedonobacteria	Thermoflexia	Thermomicrobia
Morphology	Filamentous	Filamentous	Filamentous	Filamentous	Disc-shaped coccoid	Filamentous (forming mycelia)	Filamentous	Irregular rod-shaped
Habitat	Hot springs, Ponds, Brackish waters	Anaerobic digesters, Hot springs, Submarine sediment	Costal hydrothermal field	Hot springs, Hot aquifer	Contaminated environments (digester sludge, sediments, or aquifers)	Soil, Fallen leaves on geothermal soil	Hot springs	Hot springs, Sewage sludge, Nitrifying reactor
Gram stain	Negative	Negative	Negative	Negative	Negative	Positive	Negative	Positive/Negative
Thermophily	Thermophilic or mesophilic	Thermophilic	Thermophilic	Thermophilic	Mesophilic	Mesophilic	Thermophilic	Thermophilic or Moderately thermophilic
Phototrophy	±	± ^a	–	–	–	–	–	–
O ₂ requirement	Facultative or anaerobic	Anaerobic	Facultative	Facultative	Anaerobic	Aerobic	Facultative (microaerophilic)	Aerobic

^aNo phototrophic isolate has been obtained, but culture-independent analyses revealed that an uncultured phototroph putatively affiliated with the class *Anaerolineae* thrived in a hot spring microbial mat.

Caldilineae as facultative anaerobes, can switch between aerobic and anaerobic pathways (Table 1). The difference between the strictly anaerobic metabolisms of *Anaerolineae* and *Dehalococcoidia* is that the former contain a fermentative metabolism, while the latter perform anaerobic respiration of halogenated organic compounds (organohalide-respiration). No other metabolism has been observed in any of the *Dehalococcoides* isolates. However, recent genome analyses of uncultured *Dehalococcoidia* members have indicated more metabolic diversity, such as the potential to oxidize complex organics, ability to fix CO₂, conduct anaerobic respiration or to conserve energy as ATP via substrate-level phosphorylation.

Strictly aerobic chemoheterotrophic metabolism is found in the classes *Ktedonobacteria*, the order *Herpetosiphonales* within the class *Chloroflexia*, the *Thermoflexia* and *Thermomicrobia*, and the unaffiliated isolate *Thermobaculum terrenum* (Table 1). Members of the class *Ktedonobacteria* are further characterized by their filamentous cell morphology forming branched mycelia with spores. They grow chemoheterotrophically under obligatory aerobic conditions at either mesophilic or thermophilic conditions. Some have been shown to oxidize carbon monoxide.

Members of the *Thermomicrobia* differ from the majority of the *Chloroflexi*, as they display non-filamentous cell morphology and unusual chemotrophic metabolisms (Table 1). Some members of the *Thermomicrobiales* have been shown to oxidize carbon monoxide, and although autotrophic growth has not been observed in the laboratory, the capability for CO₂ fixation was suggested by genome analysis of *Thermomicrobium roseum*. The most unusual member, however, is *Nitrolancea hollandica*, the first nitrifying (nitrite-oxidizing) member of the *Chloroflexi*. It grows obligately aerobically under chemolithoautotrophic conditions, using nitrite as electron donor and CO₂ as carbon source.

Members of the *Herpetosiphonales* are exceptional as they are known as ‘predatory microbes’. Grown on agar plates in vicinity of other bacteria, *Herpetosiphon* species have been shown to destroy whole colonies of several species of microorganisms. For killing other microbes, they appear to utilize a ‘wolf pack’ strategy, in which a large number of predatory *Herpetosiphon* cells congregate in order to lyse the prey by the secretion of hydrolytic enzymes. Members of this genus also have been suggested to be competent producers of bioactive secondary metabolites with potential use in medical or biotechnical applications.

Fig. 4 Sequential photographs of aggregate formation in *Cfl. aggregans*. The cells which had been uniformly suspended within a liquid medium at 0 min were quickly aggregated under phototrophic growing condition, and a dense aggregate was formed. Image: S. Fukushima.

aggregation speed is accelerated by exogenous protease which is produced by other bacteria coexisting with *Cfl. aggregans* in microbial mats, suggesting that the aggregation should be a response for protecting the population of the cells from predation by proteases. Cyclic AMP is likely to play a key role in control of the tactic movement, because the aggregation is also promoted by increased intracellular concentration of cyclic AMP. Mesophilic non-phototroph *Herpetosiphon* species are known as predators utilizing a 'wolf pack' strategy as described above, which may be supported by gliding motility.

Supplementary material related to this article can be found online at [doi:10.1016/B978-0-12-811736-1.20771-X](https://doi.org/10.1016/B978-0-12-811736-1.20771-X).

Although the mechanical and molecular system of gliding motility in this phylum has not been completely elucidated, recent and ongoing studies indicate a possible involvement of pili observed on the cell surface of different *Chloroflexus* spp. Once the extended pili grip the ground surface, the cells are pulled forward by the retraction of the pili (Fig. 5, Video 2). A similar mechanism has been proposed for gliding motility in multicellular *Cyanobacteria*; and is possibly shared with *Chloroflexus*.

Supplementary material related to this article can be found online at [doi:10.1016/B978-0-12-811736-1.20771-X](https://doi.org/10.1016/B978-0-12-811736-1.20771-X).

Ecology

The phylum *Chloroflexi* comprises taxonomically and physiologically highly diverse bacteria which inhabit a wide range of natural and engineered environments including microbial mats, the deep oceans, freshwater aquifers and lakes, soils, as well as bioreactors and wastewater treatment plants; they have even been recognized as constituents of the human microbiome (Fig. 6). The phylum has been recognized as a typical ubiquitous bacterial taxon, which contains a number of diverse uncultured 16S rRNA gene sequences in a wide range of temperature (0–65°C) and salinity environments, where they most likely play significant ecological roles.

Microbial Mat Environments

Microbial mats are laminated biofilms, and a wonderful opportunity to see and observe the 'unseen majority', as they harbor purely microbial communities of *Bacteria* and *Archaea*, and sometimes also eukaryotic microorganisms. Microbial mats develop under conditions which are too extreme for most eukaryotes to thrive, such as thermal springs, sulfidic and/or high salinity environments. These structures provide a three-dimensional habitat in which metabolically diverse microbial populations closely coexist and interact. The microenvironment in these habitats is characterized by steep biogeochemical (e.g., O₂, pH, redox) gradients with a number of microhabitats in which different species and populations can live. *Chloroflexi*, and especially FAPs, are common members of phototrophic microbial mat communities, especially those associated with hot spring waters between 40–70°C. In these mats, oxygen tolerant phototrophic *Chloroflexaceae* can be found co-existing with *Cyanobacteria*, but also as dominant phototrophs in *Cyanobacteria*-free mats. Phototrophic microbial mats associated with neutral and alkaline hot springs can be observed all over the world and have been extensively studied in the USA and Japan since the 1960s. Those were the first environments in which phototrophic *Chloroflexi*, back then termed 'green non-sulfur bacteria' (GNSB), were detected and isolated from. The ecological role

Fig. 5 Schematic drawing of the proposed mechanism for gliding motility in *Cfl. aggregans*. A glass bead attached to the cell-surface is moved on the cell surface by bi-directional pili retraction. If the extended pili is to grab a solid surface instead of the glass bead, the filament would be pulled over the surface by the retraction of the pili. Image: S. Fukushima.

Fig. 6 Examples for natural environments for *Chloroflexi*. Members of this phylum have been found in marine habitats, such as seawater, sponges, and deep sea sediments, microbial mats associated with extreme environments, e.g., hot springs such as Grand Prismatic Spring in Yellowstone National Park, as well as freshwater habitats such as the Great Lakes and wastewater treatment plants. (A) Available at: <https://pixabay.com/en/wave-atlantic-pacific-ocean-huge-1913559/>, (B) Available at: https://commons.wikimedia.org/wiki/File:Grand_Prismatic_Spring,_Yellowstone.jpg, (C) Available at: https://commons.wikimedia.org/wiki/File:WWTP_Antwerpen-Zuid.jpg, (D) Available at: http://www.nautiluslive.org/sites/default/files/styles/photoswipe_display/public/originals/photos/2013-06-26/cam2_20130625235339.jpg?itok=Q_ciqSFH, (E) Available at: https://en.wikipedia.org/wiki/Great_Lakes#/media/File:Great_Lakes_from_space_crop_labeled.jpg; http://visibleearth.nasa.gov/view_rec.php?id=793. (F) Available at: [https://commons.wikimedia.org/wiki/File:Aplysina_fistularis_\(Yellow_Tube_Sponge\)_behind_Amphimedon_compressa_\(Erect_Rope_Sponge-_red\).jpg](https://commons.wikimedia.org/wiki/File:Aplysina_fistularis_(Yellow_Tube_Sponge)_behind_Amphimedon_compressa_(Erect_Rope_Sponge-_red).jpg).

for phototrophic *Chloroflexi* in these mats is primary and secondary production. Despite the fact that most phototrophic *Chloroflexi* in the laboratory don't show autotrophic growth, active CO₂ fixation by those mat members has been shown to occur in the mats. The most likely growth mode in their natural environments when growing with *Cyanobacteria* is a so-called 'mixotrophic' growth, in which small organic molecules and CO₂ are taken up and utilized as carbon sources simultaneously. In purely anoxygenic mats which develop in elevated temperatures and under more sulfidic conditions, under which the growth of *Cyanobacteria* is inhibited, phototrophic *Chloroflexi* are predicted to act as the main primary producers and thus to supply the mat with organic carbon. Up to now, there has been no evidence that *Chloroflexus* spp. or other phototrophic *Chloroflexi* are able to grow in acidic (< pH 6) or brackish-saline hot springs.

In addition to neutral to alkaline thermal environments, *Chloroflexi* have been observed also in marine and hypersaline microbial mats, in which they often represent the most abundant community members. The best studied hypersaline microbial mats are located in Baja California Sur, Mexico. In contrast to hot spring microbial mats, hypersaline microbial mats are highly diverse ecosystems, which also may contain a range of protistan, metazoan and invertebrate consumers. The phototrophic *Chloroflexi* inhabiting these mats resemble green FAPs, but were shown to be phylogenetically different from the thermophilic *Chloroflexus* species. They have been observed in a variety of marine and hypersaline environments since the 1980s and are referred to as 'Marine *Chloroflexus*-like Organisms' (MCLOs) in the literature. In their natural environments they co-occur with other salt-loving phototrophic bacteria of the phyla *Proteobacteria*, *Chlorobi* and *Cyanobacteria*, but also with e.g., non-phototrophic sulfur-oxidizing bacteria, such as *Beggiatoa*. One representative of this MCLO group, "*Candidatus Chlorothrix halophila*", has been cultured in the laboratory in a stable co-culture and studied in detail. It resembles other green FAP, such as *Chloroflexus* spp. in its phototrophic properties as well as gliding motility. In intertidal sandy sediments migration of MCLOs has been observed most likely following the light. Unlike *Chloroflexus* spp. MCLOs require between 5%–12% NaCl for growth, which occurred best at mesophilic temperatures of about 35–38°C and only at a narrow pH range of 7.5–8.0. Photoautotrophic growth in the laboratory implies an ecological role as primary producer in their natural environments. This carbon fixation activity depended on sulfide, for which '*Candidatus Chlorothrix halophila*' showed an exceptionally high tolerance (up to 100mM). In their natural environment MCLOs live closely together with sulfate-reducing bacteria which produce sulfide as end-product of their anaerobic sulfate-respiration. High concentrations of sulfate as are typically found in marine and hypersaline environments also lead to high sulfide concentrations, which MCLOs seem to be suitably adapted to.

In addition to phototrophic *Chloroflexi*, also non-phototrophic members, e.g., of the *Anaerolineae* inhabit microbial mats. Their ecological role in these communities, however, has not been revealed yet. But their predicted chemotrophic metabolism indicates involvement in the degradation of organic matter and a role in carbon and other nutrient cycling.

Marine Environments

Aside from marine and hypersaline microbial mats, *Chloroflexi* have also been detected in a number of other marine environments, such as associated with marine sponges, sediments and deep water habitats. In these habitats, *Chloroflexi* do not necessarily dominate the microbial communities, but constitute only one of many phyla present.

Marine Sponges

Chloroflexi have been shown to be regular inhabitants in marine sponges, especially so-called HMA (high microbial abundance) sponges, sometimes also called 'bacteriosponges', where they co-dominate the microbial community together with *Acidobacteria* and members of the "*Candidatus Poribacteria*" phylum, as well as a variety of other phyla present. An enormous diversity of estimated 14–25 genera and 17–31 species of *Chloroflexi* seem to be specifically associated with these marine animals. *Chloroflexi* living in sponges belong to the classes *Caldilineae* and *Anaerolineae*, as well as to the uncultured environmental SAR202 clone group related with the *Dehalococcoidia*, but none is closely related to any isolated members of this phylum. Ongoing genomic analyses revealed aerobic chemoheterotrophic metabolisms for these sponge-associated *Chloroflexi* and specifically carbohydrate degradation in *Anaerolineae* and *Caldilineae* members, while the SAR202 members have the ability to produce vitamins and co-factors with potential benefit to the sponge host. These studies suggest that sponge symbionts collectively engage in the degradation of this dissolved organic matter, and thus contribute to DOM (dissolved organic matter) re-cycling and primary productivity in reef ecosystems via a pathway termed the 'sponge loop'.

Marine Sediments

Chloroflexi-related bacteria affiliated with the *Dehalococcoidia* have been repeatedly found in different marine sediments worldwide. High relative abundances of this group, sometimes up to 80% of all bacterial ribosomal gene sequences obtained, has been described in sediment samples all over the world. None of the widely distributed marine *Dehalococcoidia* members have been cultivated yet, and little is known about their physiological properties. The co-existence of a great variety of different *Dehalococcoidia* phylotypes within the same habitats indicates varying metabolic properties within this group. Further, differences between abundance and presence of specific clades with depth may relate to changes in biogeochemical factors and thus indicate specific adaptations to the corresponding environments, e.g., available electron donors and acceptors, and carbon sources. Genomic studies

have revealed some insights into possible metabolic functions. Unlike all isolated *Dehalococcoidia* members, the inhabitants of marine sediments do not seem to have the ability to perform reductive dehalogenation, contained a significantly larger genome size, and a greater metabolic versatility with metabolic potential. Genes for oxygen protection, which are all absent in isolated *Dehalococcoidia*, might represent adaptations to growth in shallow marine sediments where these organisms can be expected to periodically be exposed to oxygen. Additionally, the ability to oxidize reduce sulfur compounds has been proposed for members of this group, indicating a role in sulfur cycling. Overall, a wider metabolic and genomic diversity is now expected within this group, which also contributes to their widespread occurrence in the marine subsurfaces.

In addition to *Dehalococcoidia*, also *Anaerolineae* and *Caldilineae* members as well as the SAR202 clade have been detected in marine subsurface environments. *Anaerolineae* and *Caldilineae* sequences were found to be especially dominating in deeply buried sediments of more than approx. 1 m depth, where they often co-exist with members of the uncultured JS-1 group. Based on the chemoorganotrophic anaerobic metabolism of isolated *Anaerolineae*, contribution to terminal organic matter mineralization processes is also suggested for the uncultured *Anaerolineae* members in the deep biosphere. Further, indications for the metabolic ability for sulfate reduction and iron utilization have been found in an *Anaerolineae*-related partial genome.

Deep Ocean Environments

The environmental gene cluster SAR202, also 'Chloroflexi subphylum IV', has first been detected in early investigations of seawater and since then been recovered from a variety of environments; they are consistently identified in the marine oceans where they constitute up to 10% of the bacterioplankton. It was the first microbial lineage discovered to specifically inhabit the dark, aphotic zones of the oceans, below the deep chlorophyll maximum where they are highly abundant and were found to persist down to 3600 m in the Atlantic Ocean and to 4000 m depth in the Pacific Ocean. Based on recent metagenome studies, the SAR202 cluster contains two distinct clades which members are suggested to be free-living chemoheterotrophic organisms with medium sized cells. They most likely metabolize multiple organosulfur and other organic compounds, possibly have the ability oxidize sulfite, and are predicted to play a major role in sulfur turnover in the dark water column.

Freshwater Environments

Chloroflexi have been detected in a wide range of natural and human-made freshwater environments, such as lakes, aquifers, sediments, lagoons and wastewater treatment plants. Most of the detected cultured and uncultured representatives in these habitats have been affiliated with the 'subphyla I', thus the *Anaerolineae* and *Caldilineae*, 'subphylum IV', i.e., the SAR202 clade, but also the 'subphylum III', the *Chloroflexia*.

Pelagic Freshwater

Freshwater bacterioplankton also often contains members of the *Chloroflexi* phylum, although often not as dominant taxa (average: 1%, range: 0%–4%), most of them affiliated with 'subphyla I and IV', i.e., the classes *Anaerolineae/Caldilineae* and the SAR202 clade. Overall, genomic diversity of pelagic freshwater taxa within the *Chloroflexi* is remarkably diverse; however communities living in the deeper layers of stratified lakes, the hypolimnion, have been shown to be less diverse than the upper layer, the epilimnion. Two clusters repeatedly detected in the he hypolimnion are affiliated with the uncultured CL500–11 cluster within the class *Anaerolineae*, and the unaffiliated TK10 cluster. In oxygenated hypolimnions of lakes such as the Laurentian Great Lakes and Crater Lake (USA), as well as Lake Biwa (Japan), *Chloroflexi* can dominate the bacterioplankton community. Members of the uncultured CL500–11 clade are among the largest prokaryotic cells in the water column of deep lakes. Based on genome reconstruction from metagenomic data, they are predicted to have an aerobic, motile, heterotrophic lifestyle with the additional capability to use light via bacteriorhodopsin and one-carbon compounds; and are believed to contribute significantly to deep lake carbon flow. In contrast to the CL500–11 clade, there is very little ecological information on the other *Chloroflexi* repeatedly found in freshwater lakes, the uncultured hypolimnion specific class-level TK10 cluster, and the epilimnion-specific uncharacterized class-level SL56 clade.

Freshwater Sediments

Chloroflexi have also been detected in freshwater sediments from lakes and rivers, where they constitute between 5%–25% of the bacterial communities. Most of those *Chloroflexi* have been affiliated with the 'subphylum I' (*Anaerolineae/Caldilineae*) and 'subphylum II' (*Dehalococcoidia*), but some also with undescribed new subphyla/classes. Based on the isolated members of the *Dehalococcoidia*, an environmental role involving the degradation of halogenated solvents and organics is predicted. However, metagenome studies conducted from terrestrial aquifer sediments which covered partial genomes of *Chloroflexi* members from 15 distinct lineages, found genes for organohalide respiration to be rather rare. Near complete genomes suggest aerobic chemoheterotrophic respiratory metabolism for an uncultured lineage in the *Anaerolineae*, and proposed roles in sugar and plant-derived-compound degradation for two uncultured class-level clades related to the *Dehalococcoidia*. Overall, *Chloroflexi* in those aquifer sediments were abundant and highly diverse, with possible roles in carbon cycling by respiration of sugars, fermentation, CO₂ fixation and acetate production via acetogenesis.

Wastewater Treatment Plants and Bioreactors

Filamentous *Chloroflexi* have long been observed in wastewater treatment plants. The interest on bacteria in these environments were mainly driven by the search for causes and control of activated sludge bulking, foaming and other solids separation problems. Many were described only based on microscopic studies and given different 'morphotype' numbers by Eikelboom (e.g., Eikelboom morphotype 0914, now termed '*Candidatus Sarcinathrix*'). Most belong to the classes *Anaerolineae* and *Caldilineae*, but also represent other, uncultured, class-level clades in 'subphylum I', which are being characterized *in-situ* by microscopy and genome analyses. *Chloroflexi* have been demonstrated to be constituents of mesophilic and thermophilic anaerobic (methanogenic) as well as activated sludge systems, and other bioreactors treating municipal wastewater; but also wastewaters containing compounds recalcitrant to biodegradation, such as phenol, phthalates, benzoate and others, as well as microbial fuel cell systems, e.g., fed with cellulose. Also nitrifying systems were shown to contain *Chloroflexi* in abundance, such as the nitrifying *Thermomicrobia* member *Nitrolancetus hollandicus*. The wide range of human-made environments, their high abundance and often dominance within these strongly suggest an indispensable role and ecological significance as well as physiological diversity of *Chloroflexi* in these habitats. Based on physiological properties of isolated strains from these habitats, it has been suggested that they may contribute, e.g., to the degradation of carbohydrates and other cellular components, such as amino acids, in the bioreactors. *Chloroflexi* of the 'subphylum I', and especially their filamentous morphology, are further considered important for the granulation of sludge in those bioreactors which is a major premise for the start-up and stable operation; while some have been suggested to be responsible for impaired sludge settleability known as 'bulking' which proposes an operational problem in the systems.

Soils

Although not the most dominant phylum, *Chloroflexi* can be considered as one of the dominant taxa in soils. On average it has been found to be the sixth out of nine abundant phyla, with an average of 3% (range 0%–16%). However, *Chloroflexi* in soil have not been thoroughly studied and data on physiology and ecological importance for these soil inhabitants are rare. One study found a correlation of *Dehalococcoides*-like *Chloroflexi* with the concentrations of organochlorine compounds in soils pointing towards an ecological role of organohalide-respiring *Chloroflexi* in the biogeochemical chlorine cycle in soils. Isolation studies showed that soil *Chloroflexi* affiliated with the uncharacterized E05 (within TK10) and G04 (within SL56) clades were rather slow-growing and mini-colony forming, pointing at the cultivability of these uncultured groups with sufficient patience by the scientist.

Human Microbiome

A distinct group of uncultured *Chloroflexi* related to free-living anaerobic *Anaerolineae* has been reported as a low abundance (<1%) but consistent component of human oral and skin microbiota, as well as the gut of other mammals. They are considered to represent a minor component of the overall healthy human microbiota. However, in some cases, *Chloroflexi* have been associated with diseases, such as periodontitis, an inflammation of the gums and supporting structures of the teeth, where they were found to proliferate in the subgingival pockets of the patients. The 'oral taxon 439' group is closely related to the recently described *Flexilinea flocculi* (class *Anaerolineae*). Similar to *F. flocculi* and other isolated members of the *Anaerolineae*, single-cell genome studies indicate the oral *Chloroflexi* to be anaerobic chemoheterotrophs. Their genomes encode abundant carbohydrate transport and metabolism functionalities. Other genes suggest an important ecological niche for the oral *Chloroflexi* in scavenging material from lysed bacterial cells and human tissue. Their ability to produce sialic acid, which is widely distributed in animal tissue, may enable them to hide from the host defense system and then colonize the subgingival space and to proliferate in periodontitis.

Genomics

With the invention of Next-Generation-Sequencing methods, prices for genome sequencing dropped significantly over the past two decades and the numbers of genomes available in public databases increase continuously. At the time of writing (July 2018), the databases of the "National Center for Biotechnology Information" (NCBI) listed 426 genomes for the phylum *Chloroflexi*, while the databases of the 'Joint Genome Institute' (JGI) contained 310 *Chloroflexi* genomes (Table 2). Most of the published genomes belong to uncultured and unclassified *Chloroflexi* and (often also uncultured) members of the class *Anaerolineae*.

The majority of these genomes are still in the process of being thoroughly analyzed and published. A quick search in literature databases, such as 'Web of Science' or 'PubMed', but also in 'Google Scholar' will reveal any early and most recent literature.

Early genome studies focused on pure culture isolates. Those studies allowed elucidation of pathways and metabolic capacities beyond the ones observed in the laboratory. Genome analysis of FAPs, for example, suggest their capability to fix CO₂ via the 3-hydroxy-propionate bi-cycle even for those strains that do not express this trait under laboratory culture conditions. The verification of this hypothesis is currently underway by isolation studies demonstrating autotrophic growth in several *Chloroflexus* spp. strains.

With the increasing power of sequencing techniques, the decreasing prices as well as the increase in available computing power environmental genomics have revealed valuable information also about uncultured members of this phylum. Of the approx. 25–30 or more *Chloroflexi* classes, only eight contain isolated members. Only thanks to environmental metagenomics we are learning about the metabolic potential of representatives of lineages previously characterized only by 16S rRNA gene sequences. In an aquifer

Table 2 Number of genomes listed for the different classes in the phylum *Chloroflexi* in the NCBI database

Taxon	Genomes
Phylum <i>Chloroflexi</i>	426
Class <i>Anaerolineae</i>	134
Class <i>Ardenticatenia</i>	3
Class <i>Caldilineae</i>	5
Class <i>Chloroflexia</i>	13
Class <i>Dehalococcoidia</i>	89
Class <i>Ktedonobacteria</i>	6
Class <i>Thermoflexia</i>	1
Class <i>Thermomicrobia</i>	5
unclassified <i>Chloroflexi</i>	170

sediment environment the analysis of uncultivated *Chloroflexi* members indicate a complex set of potential roles of these *Chloroflexi* in sediment carbon cycling, including organohalide and sugar respiration, as well as fermentation, CO₂ fixation and acetogenesis. Genome analyses also enable insights into the evolution of life, bacteria and functional traits. Comparative genomics, for example, suggests that horizontal transfer of genes encoding a nitrite oxidoreductase (NXR) was a major driver for the spread of nitrite oxidation during bacterial evolution.

Glossary

anticontagionism The belief that disease originates not from the transmission of germs from person to person but rather from interaction with an unsuitable environment, contact with rotting or deteriorating organic material, inhalation of polluted or contaminated air, or immoral behaviors.

contagionism The belief that disease is transmitted by direct or indirect contact between living organisms, especially humans, in the form of microscopic living entities (e.g., germs).

miasma Literally, foul or bad air arising from decaying animal or vegetable matter, thought by anticontagionists to cause disease.

quarantine Originates from the Italian words *quarantina* and *quaranta giorno*, referring to the 40-day period ships entering the port of Venice were required to remain in isolation before any disembarkment. Defined by public health authorities in the nineteenth century as the process of inspecting all ships, cargos, and passengers for evidence of contagious diseases.

sanitarians Public health officials who worked to eradicate disease by disinfecting the environment and imposing sanitary restrictions on citizens.

Defining Statement

Cholera is an acute diarrheal disease in which *Vibrio cholerae*, serogroup 1, found only in humans, are present in large numbers in the small intestine. Marked by severe abdominal pains and rapid dehydration, cholera has brought horrific and untimely death to millions as it swept the world in as many as seven pandemics in the past two centuries. Cholera's modern history as a worldwide pandemic disease begins in 1817. Long endemic in India, cholera at this time began to make its way out of the subcontinent and spread as far as the United States by 1832. Cholera, described by one historian as 'the classic epidemic disease of the nineteenth century', has played a major role in medical history, particularly due to its widespread physical and emotional effects on individuals, societies, and cultures. The disease manifests with little warning, induces frightfully painful symptoms in its victims, and kills between 30 and 80% of those infected. Moreover, the cholera pandemics spanned generations, crossed political and geographic boundaries, and fueled fears of disease during a time of dramatic growth in the life sciences, public health, and international migration.

Etymological Considerations

The Greek word *kholera*, meaning 'bile' or 'to flow', is found in sources as early as the Hippocratic Corpus. Classical writers such as Celsus (first century AD) used the term 'cholera' to describe illnesses marked by sporadic diarrhea, vomiting, and gripping abdominal pain. Although this term has been in use for millennia, it was applied in various ways to describe a variety of conditions. For example, the term 'choleric', meaning 'easily moved to anger', is also derived from *kholera*, but was a concept employed by humoralists to describe the condition resulting from vitiated humors. It was not until 1669 that Thomas Sydenham first used the term 'cholera morbus' to distinguish sporadic and endemic diarrhea from the choleric concept. By the early nineteenth century, when cholera reached global epidemic proportions, the term 'cholera nostras' had come to designate diseases with symptoms similar to sporadic and endemic cholera (i.e., profuse diarrhea, dehydration, and cramps), whereas cholera morbus described the more virulent occurrences of epidemic cholera. Other terms synonymous with epidemic cholera are cholera asiatica, malignant cholera, cholera asphyxia, and cholera spasmodica.

Pathogenesis, Signs, and Symptoms

The disease called cholera today occurs when the etiological organism *Vibrio cholerae* is ingested and passes through the stomach into the small bowel, where it colonizes and multiplies. The *V. cholerae* is an acid-sensitive bacterium and a human must ingest a relatively large inoculum for sufficient numbers to evade the acidic environment of the stomach and reach the small intestine. The organism then releases a toxin that enters the epithelial cells, disrupting the absorption of electrolytes, and results in copious, watery discharges relatively free of fecal material accompanied by shredded mucous and epithelial cells giving it a characteristic 'rice water' appearance.

This article is a reprint of C.D. Meehan, H. Markel, Cholera, Historical, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 24–29.

The signs and symptoms of cholera are the result of a rapid loss of fluid and electrolytes. Symptoms begin with the victim's sense of generally not feeling well. This condition lasts only a few hours and is then followed by a violent bout of vomiting and diarrhea. The victim experiences painful spasms of the abdominal muscles as a result of forceful propulsions of the gut, and matters only worsen as hypovolemic shock ensues. The effects of dehydration are painfully apparent on the face of the victim; the skin becomes blue and tight, the eyes are sunken deeply in their sockets, and the lips and mucus membranes of the mouth are dry and cracked. As diarrhea and vomiting continue, patients become increasingly more disoriented and eventually lapse into convulsion and/or coma. From 30 to 80% of all cholera cases end in death.

Etiology

From antiquity until well into the nineteenth century, the medical theory of the cause of cholera was relatively static. For the most part, illness was perceived as an imbalance in the bodily humors due to poor diet, change in weather or seasons, geographic environment, or exposure to poisoned air or miasmas, such as the foul air caused by rotting organic material or animal and human waste. Although humoral theory waned during the nineteenth century, miasmatic theory and environmental influences continued to serve as explanations for disease. In a world still influenced largely by religious morality, people also often invoked metaphysical conceptions to explain cholera and other diseases. In America during the 1830s, for example, many ministers, moralists, and physicians agreed that those suffering from cholera had engaged in sinful activities and thereby predisposed themselves to sickness.

When the second pandemic reached Europe and the United States (1832), delegations of scientists and physicians were sent out to study the spread of cholera, and questions about its contagious nature slowly began to surface. Germ theory was far from well established at this time, but burgeoning interests in contagionism and increasing knowledge of microorganisms stirred the imagination of medical scientists to search beyond the traditional metaphysical and environmental explanations of disease.

Perhaps one of the greatest challenges to miasmatic theories on the cause of cholera came from John Snow, a British physician and epidemiologist. In the summer of 1849 he published a pamphlet "On the Mode of Communication of Cholera", in which he proposed that cholera was a waterborne disease. In 1854, his theory would be put to the test. He mapped incidences of cholera that occurred near Golden Square in London and noted that many cases were clustered around a particular water pump on Broad Street. After careful analysis, his cholera pamphlet was expanded and reprinted in 1855, reporting findings that sewage had seeped into the well that the recent victims of cholera used and concluding that contaminated water was the 'predisposing cause' of cholera. Although Snow was unaware of the causative agent, he posited that *materis morbi* (poisonous matter) must have caused the infection. Although many papers and pamphlets were published on studies similar to Snow's (such as the work of William Budd) and some measures were taken to avoid contaminated water, many medical and scientific elites who subscribed to anti-contagionist theories, such as the German public health expert Max Von Pettenkofer, remained resolute in their belief that cholera was caused by imbalances in the air, soil, and environment or exposure to human and animal filth in overcrowded cities. Shortly after Snow announced his findings, Italian microscopist Filippo Pacini reported his discovery of a microorganism with a terminal flagellum, isolated from the excreta of a cholera victim. This report, however, did not attract much interest among the medical community. Moralistic ideas and claims about miasmatic theory were slow to die.

Anticontagionism, however, steadily lost scientific credibility as the nineteenth century progressed. For example, in 1868, the French chemist Louis Pasteur first articulated the germ theory when he elucidated the microbial cause of silkworm diseases. Fifteen years later, the famed microbiologist Robert Koch isolated the *V. cholerae* during the cholera epidemics in Calcutta and Alexandria. Indeed, Koch's studies confirmed that cholera is transmitted through drinking water and food contaminated with fecal matter from those infected with cholera.

The acceptance of germ theory and rapid growth in the science of bacteriology yielded more advances in the field of cholera research at the turn of the century. Recent investigation has elucidated the existence of 60 or more serogroups of *V. cholerae*, of which only a single group, serogroup 1, is responsible for the epidemic cholera; others are responsible for sporadic diarrhea and symptoms similar to epidemic cholera. Serogroup 1 of the *V. cholerae* exists as two serotypes, Ogawa and Inaba, each characteristic of different somatic antigen structures in the organism. *V. cholerae* also occur as two major biotypes: the classic (first described by Koch) and El Tor. The El Tor vibrio was discovered in 1905, during the sixth pandemic, in the El Tor quarantine camp in Egypt. Six unusual strains of vibrios were isolated from the dead bodies of pilgrims returned from Mecca. Gotschlich, who isolated the strains, performed tests that revealed the reactions of classic *V. cholerae*, though the victims did not show any signs of the cholera disease post mortem or while they were alive. Upon reexamination of the strains, Kraus and Pribram found that the El Tor vibrios produced a hemotoxin found to be lethal in experimental animals. They hypothesized that variability in the biotypes could be responsible for individual cholera epidemics. This was clearly demonstrated in the 1960s when El Tor was found to be the cause of many cholera outbreaks throughout the world.

The previous hypothesis was further supported in early 1993 when a *V. cholerae* strain, with an antigenic structure differing from that of El Tor, was found responsible for a large outbreak in India. The existence of the newly identified strain, named O139 Bengal, demonstrates that epidemic potential is not exclusive to the classic and El Tor vibrios bearing the O1 antigen. The existence of O139 Bengal is indicative of an emerging level of complexity in the relationship of genetic and epidemiological factors facing today's researchers and public health officials.

The Pandemics

First Pandemic (1817–1824)

In 1817, northeastern India experienced a particularly heavy rainfall that brought deluge to the state of Bengal and other regions between the Ganges and Brahmaputra Rivers. Floods resulted in failed crops and destroyed villages, and following the devastation cholera appeared with extraordinary virulence. In July of that year, cholera broke out in several districts in Bengal. Within a month, 25 000 people in Calcutta were being treated for the disease, 4000 of whom perished. This episode marks the beginning of cholera as a worldwide pandemic disease. Only 3 months later the province of Bengal was consumed by the disease, and by 1818 cholera extended in all directions to Nepal, Burma, and further into India: Delhi, Bombay, and as far as Ceylon. Although cholera affected these regions in the past, the rapidity with which it spread and the numbers mortally endangered in 1817 cast a shadow over any previous record of the disease. By 1820, the disease had spread by sea and land routes to Southeast Asia, moving from Burma to Siam's (Thailand) capital city of Bangkok and to Indonesia, where as many as 100 000 people succumbed to the cholera menace.

By 1822, incidences of cholera began to subside in India, although the disease was widely established outside the subcontinent. Ships traveling from Southeast Asia carried the epidemic to China, where it had been previously introduced by land travelers as early as 1817. Soon after, the British army landed infected troops from Bombay into Oman, Arabia, from where the disease spread and was established in Muscat by 1821. In the same year, 15 000–18 000 people were killed along the Persian Gulf in port cities such as Basra. From this region cholera continued on, moving across the Mediterranean region, carried by caravans into countries such as Syria, where it raged until the end of 1823. The spread of cholera was greatly facilitated by Persian troops victoriously returning home to present-day Iran after warring with Turks; they served as vectors for the deadly vibrio, disseminating cholera in areas between the Tigris and Euphrates Rivers.

After raging across the Far and Middle East for as many as three or four seasons, cholera subsided but remained active in Lower Bengal, India. Some have posited that control measures may have been responsible for cholera's retreat in the early 1820s, although others have ascribed its decline to a severe winter during 1823 and 1824.

Second Pandemic (1829–37)

By 1824 cholera settled back in its home, the endemic area of the Ganges Delta in Bengal, India. There the disease remained active until 1827, when it was reported to have moved west to the Punjab. Cholera continued to exist in isolated regions outside of India during the interpandemic period; therefore, when the disease spread to the north and west of the Caspian Sea, into Russia and neighboring countries, it was thought that the pandemic's origin came from Astrakhan, Azerbaijan, where cholera had persisted throughout the 1820s. However, cholera did not disperse from Astrakhan until 1830, although it was observed to be a problem in Orenburg, Russia, as early as 1829. Reports from that period in China demonstrated that the second pandemic made its way back into areas of China, particularly in and around Peking, via India, and from there gradually extended into Russia. Similarly, cholera was creeping across Persia from Afghanistan into Russia by way of caravans. Although these scenarios might not explain cholera's appearance in Orenburg, they demonstrate the vast space through which cholera steadily advanced early in the second pandemic.

Well established in Russia by 1830 in cities such as Moscow and Kharkov, cholera was then introduced into Poland by the Russian army. A ship transported the disease from Riga to the Prussian city of Danzig, resulting in a wave of infection that soon spread to Berlin, Vienna, and Hamburg by late 1831. At this time, some of the first cases of cholera were appearing in England in the port city of Sunderland, which had shipping connections with Germany. Cholera effectively made its way through England in 1832, infecting as many as 15 000 people and leaving more than one-third of them dead. The same year cholera visited Ireland and France. All of Paris' districts were reportedly overcome with the disease and as many as 7000 people died in 18 days. By early 1832, much of Europe was suffering from the devastating effects of cholera. Having traveled from Asia through the Near East and into Europe, it crossed the Atlantic and released its fury in North America. On 8 June, a ship from Dublin carried 173 passengers to Quebec City and Montreal, of which 42 died before reaching port. On 23 June, cholera appeared in New York, and 2 weeks later it surfaced in Philadelphia. From the north the epidemic spread to Mexico, Latin America, and the Caribbean. It was not until 1837 that the second cholera pandemic finally subsided.

Third Pandemic (1846–55)

Scholars have long debated the dates of the second and third pandemics. Authorities such as Pollitzer considered the second pandemic to have run until 1851, marking the commencement of the third in 1852. Others, however, noting the significant decrease in cases of cholera and its withdrawal in some areas during the period of the mid-1830s to the mid-1840s, have concluded that the resurgence of the disease in 1846 marks the beginning of a third pandemic.

In 1846 cholera again erupted in and around the endemic regions of South Asia. Having already extended into Persia and central Asia during 1844 and 1845, Europe was again invaded by cholera by 1848 in much the same fashion as the disease progressed during the second pandemic. In the same year, New York and New Orleans were miserably reacquainted with cholera. From these cities cholera spread rapidly across North America, reaching as far as California in 1850. Present throughout Europe since 1849, cholera continued its course, eventually surging in 1854, making this year one of the worst on record.

Fourth Pandemic (1863–79)

In the fourth pandemic, cholera flourished in the same regions as it had in past pandemics, but it infiltrated Europe via new routes. Instead of moving from Asia, across Persia and the Caspian Sea, and into the heart of Europe, cholera traveled across Arabia. In Mecca, for example, 30 000 of 90 000 pilgrims died in 1865. The scourge progressed throughout the Mediterranean regions from Alexandria, Egypt, and this time entered Europe through Italy and southern France. From Egypt, Africa's countries along the eastern coast were ravaged as far south as Mozambique. When cholera traveled north in 1866, some of the worst episodes occurred in Germany; where up to 115 000 deaths were reported. In Berlin, approximately 5500 deaths occurred out of 8000 cases. It has been suggested that Austria's wars with Germany and Italy may have contributed to cholera's dissemination.

In 1866, the United States was just recovering from the Civil War when cholera returned for a third American epidemic. New Orleans was hit by several waves of cholera through 1868 and the disease spread through the South and the Midwest via the extension of the railway system. However, the outbreaks were mild in comparison with previous epidemics. In New York, measures such as the cleaning of city streets and the isolation of the ill were successful in preventing the further transmission of disease. Cholera resurfaced again in New York and New Orleans in 1873–75, though casualties were minimal. Russia, Persia, Arabia, Africa, India, and much of East Asia, however, suffered repeated serious attacks of cholera during this period. Central Europe also had its share of cases, but epidemics were less widespread due to the increasing awareness of public health.

Fifth Pandemic (1881–96)

Many of the early epidemics of this period occurred in Asia, particularly China, and around the Mediterranean. However, in 1892 Hamburg suffered a huge outbreak of cholera due to the contamination of unfiltered water from the Elbe River; approximately 7500 deaths occurred. In North America, potential epidemics were again prevented due to advanced notice and modern sanitary measures, although isolated cases were recorded, particularly in New York City.

Sixth Pandemic (1899–1923)

Cholera recrudesced in India in 1899, marking the start of the sixth pandemic. Cholera never disappeared completely from China and other regions of Asia after the previous pandemic, as was also the case for Egypt. From these regions, cholera spread to Persia, Arabia, and Afghanistan. During this period, America and most of Europe were largely unaffected, although sporadic cases occurred in southern Europe and Hungary.

Seventh Pandemic (1961–Present)

Many of the epidemics occurring in the present era have been traced to the El Tor biotype. El Tor was isolated in Indonesia and China in 1961 and in 1962 the World Health Organization recommended the inclusion of diseases caused by El Tor to appear in the definition of cholera. Both the classic and El Tor biotypes were detected in Afghanistan, from where the El Tor spread to neighboring Iran. An upsurge in cholera infection was also documented to have spread into Europe and Africa in 1970 and 1971. Since 1972, the number of countries affected in any 1 year has declined. However, in South America, where nearly a century had passed since the last reported cholera cases, the disease broke out violently in Peru in early 1991. El Tor was found responsible for this episode and for the recurrent Latin American epidemics that followed in the early 1990s. In late 1992, cholera-like disease appeared in Madras, India. The outbreak spread north into Bangladesh, where 100 000 cases were reported in the next 6 months. The new strain of *V. cholerae*, O139 Bengal, was the source of this epidemic that subsequently spread to Pakistan, Nepal, and regions of Southeast Asia. Cholera remains endemic in areas of Asia, Africa, and many countries of South and Central America, and rarely isolated cases of cholera have been imported to America and Europe. One relatively recent occurrence was reported in Los Angeles in 1993 after a woman returned from a 6-week visit to Hyderabad, India.

Geographical Considerations

Cholera owes much of its geographical distribution to pilgrimage, the industrial revolution, international shipping, traveling armies, and immigration. For example, large religious festivals in India convene near sacred sites, usually along the banks of sacred rivers. Upon people's return home from such festivals, where thousands camped and used the same water supplies, cholera often followed. A similar process has been observed during the Islamic pilgrimages to Mecca. As transportation, such as with the steamship, became more efficient and continental and intercontinental railways linked city and village, the dissemination of the disease accelerated. The need for large workforces during the industrial revolution and the desire of many to emigrate because of either political or religious persecution contributed to the crowding of cities and the contamination of water supplies.

Control, Prevention, and Treatment

Some of the most significant topics explored in the history of medicine, such as the modern-day understanding of contagious diseases, the rise of sanitation and public health institutions, and developments in medical therapy, find context in the history of

cholera. For much of the nineteenth century, doctors found that they could do very little to prevent or cure cholera. Revolutions in industry and transportation brought about the rapid growth of urban populations. It was in this setting, including the living conditions of crowded and dirty cities, contaminated water supplies, and large-scale migration of peoples, that cholera proliferated before traveling into bucolic areas. Before the 1830s, city officials had little interest in public health. With news of cholera moving from East or West, however, both European and American newspapers and popular magazines reported the spread of the disease, raising the attention of civic leaders and the public. Physicians and public health officials published pamphlets and articles and posted signs encouraging personal hygiene. Anticontagionists such as Von Pettenkofer warned of bad air and soil and encouraged proper nourishment and sanitary measures. John Snow, on the contrary, encouraged attention to maintaining clean water and Koch's discovery of the etiology of cholera, *V. cholerae*, led to the development of modern public health policies and sanitation procedures and techniques that continue to maintain health in much of the industrialized world.

One of the initial responses to cholera's appearance or impending crossing of borders was the use of quarantine. For example, soon after it was reported that cholera broke out in Canada in 1832, both Canadian and US ports issued quarantine measures on all shipping and goods. In 1892, an epidemic of cholera was effectively prevented by the quarantining of ships in New York Harbor, where infected passengers were found. Entire vessels were quarantined for days until it was certain that no cholera would be introduced to the population on land. As a result of bacteriologists' increasing abilities to recognize organisms and epidemiologist's facility to track disease, scientists, physicians, and public health officials have been successful in controlling the spread of cholera.

Treatment of cholera before and during the early nineteenth century employed the use of emetics, purgatives, and even bloodletting. Such practices probably only worsened the conditions of the ill. As early as 1830 research in fluid balance led physicians to attempt injecting water into terminally ill cholera patients. Many of these patients demonstrated the return of a strong pulse, but soon died. Injections of saltwater proved slightly more helpful, although determining a proper and effective solution was not always possible. Hence, such a treatment did not become successful until the early decades of the twentieth century when physicians had a clearer understanding of water and electrolyte balance. After the discovery of antibiotics in the 1940s, their use and a carefully planned regimen of fluid replacement greatly improved the therapeutic resources of physicians.

Cholera and Society

Epidemics are commonly viewed as crises and engender massive reactions by physicians, public health workers, and laypeople. One unfortunate theme in the history of cholera (as with other epidemic diseases) is the scapegoating of those people and social groups perceived to be the vectors of the epidemic in question. The history of immigration illustrates such examples, where massive movements of peoples resulted in the transmission of disease across borders. In large cities that attracted great numbers of immigrants, such as New York City, the meeting of various ethnic groups and cultures set the stage for dramatic shifts in civic and social organization. When dealing with the cholera menace, societies, governments, and groups such as public health organizations at times did not hesitate to point the finger at marginalized peoples, labeling them as the bearers of disease. Immigrants were perceived to be predisposed to disease based on the association with the relatively few immigrants who did arrive in US ports ill with cholera and hence stigmatized. In reality, cholera was a social leveler that attacked people of all social classes and backgrounds. Nevertheless, the fear of cholera often inspired certain majority social groups to scapegoat and blame minority groups, such as immigrants and the urban poor.

On the contrary, the cholera pandemics in the nineteenth century helped solidify ideas and sentiment toward concerns for public health in a time of scientific, economic, and societal growth. During this period, the pandemics also inspired the formation of the first international health agency (the International Sanitary Conferences), demonstrating that epidemics also have the power to bring nations together. Hence, the history of cholera illustrates that epidemic disease is an intimate part of social organization and change.

Glossary

Anaphase-promoting complex (APC) A ubiquitin ligase activated in mitosis that triggers degradation of cyclin-dependent kinases and cohesins.

Autonomously replicating sequences (ARS) Yeast chromosomal sequences that provide a replicator function to plasmids and produce high-frequency transformation. ARSs are the most thoroughly studied replication origins in yeast.

Cell cycle The life span of the cell, from cell division to cell division.

Centromere *Cis*-acting sequences that control movement and segregation of chromosomes. In eukaryotic microbes, centromeres are attached to microtubules of the mitotic spindle apparatus. In prokaryotic microbes, the centromere and its attachment structure are less well defined.

CMG complex The active eukaryotic DNA replication fork helicase comprising Cdc45, Mcm2-7 and GINS.

Cohesins Proteins holding newly replicated yeast chromosomes together until the sister chromatids become attached to spindle microtubules.

Cyclin-dependent kinase Serine/threonine kinases involved in cell cycle regulation when complexed with cyclins.

DNA unwinding element (DUE) Regions of double-stranded DNA, where the helix is easily destabilized to achieve a single-stranded state. The DUE is associated with replication origins and is rich in A–T base pairings.

DnaA-Trio element DUE-associated region in bacteria containing arrays of the nucleotide triads 3′-GAT-5′, 3′-AAT-5′, and 3′-GAA-5′. Following DUE unwinding, DnaA oligomers assembled along the trios assist in loading the replicative DNA helicase.

Equipartition Allocation of one from each pair of newly replicated chromosomes into each progeny cell.

Fluorescence in situ hybridization (FISH) Microscopy technique used to locate specific genetic sites within an intact cell. DNA probes tagged with a fluorescent protein are hybridized to fixed cells and the position of the glowing spot is determined relative to intracellular structures or other genetic sites.

Fluorescent repressor operator system (FROS) Microscopy technique used to locate specific genetic sites within an intact cell. Fluorescent-tagged proteins are bound to their cognate binding sites after inserting multiple copies of these binding sites at specific genomic locations.

Kinetochore A multicomponent DNA-protein structure that forms on centromeres to link spindle microtubules and motor proteins with centromeres on the newly replicated chromosomes.

Origin of replication Chromosomal sites that interact with specific proteins to produce unwound DNA regions required to start polymerization of new DNA from existing template.

Origin recognition complex (ORC) Multiprotein complexes associated with origins of replication throughout the cell cycle, used to recruit pre-RC.

Prereplication complexes (pre-RC) Assemblage of proteins associated with ORC that is necessary to load DNA helicase and establish bidirectional DNA replication.

Sister chromatids The two linked products of chromosome duplication in eukaryotes, each containing a newly polymerized DNA strand and a template strand formed during an earlier round of DNA replication.

Spindle Microtubules emanating from a microtubule organizing center called the spindle pole body (SPB) on each side of the yeast nucleus. The microtubules grow toward the newly replicated paired chromosomes.

Abbreviations

ABF1	ARS-binding factor
ACS	ARS core sequence
APC	Anaphase-promoting complex
ARS	Autonomously replicating sequence

CDK	Cyclin-dependent kinase
DUE	DNA unwinding element
FISH	Fluorescence in situ hybridization
FROS	Fluorescent repressor operator system
GFP	Green fluorescent protein
IHF	Integration host factor
MCM	Minichromosome-maintenance
ORBS	Origin recognition boxes
ORC	Origin recognition complex
pre-RC	Prereplicative complexes
RIDA	Regulatory inactivation of DnaA
SMC	Structural maintenance of chromosomes
SPB	Spindle pole body

Defining Statement

Chromosome replication and segregation are essential events during the microbial cell cycle. Diverse regulatory mechanisms exist to initiate new rounds of DNA synthesis at origins of replication with exquisite timing, limit initiation to only once per generation, and ensure correct partitioning of newly synthesized chromosomes into newly dividing daughter cells.

Introduction

Chromosome replication and segregation are key events during the microbial cell cycle that must be completed before a cell divides. To reproduce successfully, every cell must replicate its chromosome(s) and distinguish nascent sister chromosomes from one another. Each sister chromosome must then be physically segregated into one of two new cells prior to completion of cell division. These are not simple tasks considering the large size of microbial genomes (0.2–5 mm) and the extremely limited space these genomes occupy (0.1–10 μm^3). Yet, errors (production of chromosome-less cells) are rare ($<10^{-5}$ /cell division in *Escherichia coli* and *Saccharomyces cerevisiae*). To ensure a low error rate, microbial cells require complex and precise regulatory mechanisms to both properly time new rounds of replicative DNA synthesis and orient newly synthesized DNA with respect to fixed intracellular locations. This article is focused on the nature of molecular mechanisms that regulate chromosome replication and segregation in prokaryotic and eukaryotic microorganisms. Most examples will be taken from the bacterium *E. coli* and the budding yeast *S. cerevisiae*. Emphasis will be on assembly of DNA–protein complexes at replication origins and localization of specific chromosomal sites during segregation.

Prokaryotic and Eukaryotic Chromosomes: Replication Origin Placement and Initiation Timing

Chromosomal DNA replication initiates from specialized sites termed origins of replication. In the Replicon model presented in 1963, Jacob, Brenner, and Cuzin formalized the premise of a specialized replicator site that binds regulatory initiator proteins. This model remains essentially correct, although many details of the initiation triggering process in bacteria and yeast are not yet completely understood. It is instructive to compare and contrast current knowledge about the location, arrangement, and number of replication origins on bacterial chromosomes and yeast chromosomes. This simple comparison reveals fundamental similarities and differences between the control mechanisms in these cell types.

Bacteria

Bacterial genomes, with very few exceptions, are double-stranded, circular, supercoiled DNA molecules. Each genome contains at least one fixed site, termed *oriC*, from which DNA replication initiates. In every cell cycle, two newly initiated DNA replication forks proceed from *oriC*, moving bidirectionally until the entire chromosome is duplicated. The majority of gene transcription proceeds away from the replication origin, in the same direction as replication forks. In most species of bacteria, the fixed position of *oriC* is closely associated with genes whose products play a direct role in regulation of DNA replication (e.g., see *dnaA* below). Some bacterial replication origins, such as *Bacillus subtilis* and *Helicobacter pylori*, are bipartite due to positioning of the initiator protein gene. *E. coli*'s *oriC* and those of its close relatives remain exceptional, positioned between the genes encoding ATP synthetase and asparagine synthetase, which are not directly involved in DNA synthesis.

Since there is only one *oriC* locus on most bacterial chromosomes, the number of intracellular copies of *oriC* might be expected to fluctuate from one to two during the cell cycle. This is indeed the case for slow-growing bacteria. However, during rapid growth

under nutrient-rich conditions, bacterial doubling times are shorter than the time needed to complete chromosome replication and septation. For example, *E. coli* doubling times approach 20 min in broth containing beef extract, but approximately 60 min is required after initiation of DNA replication to produce a complete copy of the 4600 kb genome and to complete cell division. Therefore, to produce two chromosomal copies for segregation to daughter cells prior to division, rapidly growing bacteria must trigger new rounds of chromosome replication from *oriC*s before previously initiated rounds are completed. As a result, these bacteria contain dichotomously forked chromosomes that contain more copies of *oriC* per cell (as many as eight in *E. coli* at cell division) than slower growing cells. Despite the unusual appearance of chromosomes in fast-growing *E. coli* (Fig. 1), each copy of *oriC* is identical and functionally equivalent to all others. In all prokaryotes examined thus far, replication initiates synchronously from all available copies of *oriC* at the start of the DNA synthesis phase of the cell cycle.

In *E. coli*, it is possible to increase further the number of functional copies of *oriC* per cell by introducing minichromosomes, plasmids whose sole origin of replication is a cloned copy of *oriC*. Minichromosomes are governed by the same regulatory mechanisms as chromosomal copies of *oriC*, that is, all *oriC* copies replicate coincidentally with cell cycle specificity. Although it might be expected that the copy number of minichromosomes would be equivalent to the number of chromosomal *oriC*s, minichromosomes are defective for equipartition at division (see segregation, below) and are inherited as though they are clumped together. The result is that, at cell division, half the cells receive the majority of minichromosomes, and half receive few or none. After sufficient numbers of generations under selective growth conditions to remove minichromosomes-less cells, minichromosome copy number increases. Regardless of number or location, all *oriC* copies initiate coincidentally, and the cell can support more than 20 copies of *oriC* without perturbing cell growth. Clearly, based on these observations, the mechanism that regulates bacterial chromosome replication is capable of triggering DNA replication without counting the numbers of origins in the cell. In addition, it is clear that this regulatory mechanism, unlike those in eukaryotes, senses neither completion of previously initiated rounds nor cell division. Initiation of DNA replication is coupled to cellular growth rate, and mechanistically must depend on the accumulation of sufficient numbers of at least one *oriC*-binding protein required for initiation (DnaA protein, see below).

Yeast

Bidirectional replication also ensues from origins on eukaryotic chromosomes, although characterization of these sites is a far more difficult task due to the large size of most eukaryotic genomes. *S. cerevisiae* contains 16 linear chromosomes, ranging from 250 to 2000 kb with a total genomic content that is three times larger than that of *E. coli*. Despite the larger amount of DNA, the time required to replicate the yeast genome in rich media is nearly identical to the time needed to duplicate the *E. coli* chromosome. This is because the yeast genome has between 250 and 400 different origins placed 40–90 kb apart (Fig. 1). A number of yeast replication origins are available for study as autonomously replicating sequences (ARSs), but genomic origins are difficult to determine by sequence features alone, and ARS-containing DNA fragments are sufficiently different from one another in that they do not cross hybridize. Despite this fact, common sequence modules are reported (see below).

Unlike the synchronous initiations seen in eubacteria, yeast origins do not all fire at the same time (Fig. 1). Using a combination of density labeling and microarray analysis in *S. cerevisiae*, the majority of origins (332 origins spanning the genome) were observed to fire near mid-S phase, but origins in centromeric regions initiated earlier and telomeric origins initiated later than the majority of mid-S phase initiators. Although adjacent origins tend to fire at the same time, origin-firing times may be separated by as much as 20 min. There also appears to be a preferred range of origin-firing times that is distinctive for each chromosome. This is a remarkable burden to place on the initiation-triggering mechanism because origins that fire late must be identified amidst an ever-increasing background of origins that have already initiated DNA replication. Obviously, reinitiations in any single S phase are not permitted and stringent regulatory mechanisms are required to ensure once-only origin firing each cell cycle.

Fig. 1 Multiple origins of replication in bacteria and yeast. (A) In rapidly growing bacteria, multiple origins initiate chromosome replication synchronously. All origins fire before the previous round of replication is completed, resulting in dichotomous replication forks on a single chromosome. (B) In eukaryotic microbes, not all origins initiate synchronously. A single origin functions only once during S phase, and no reinitiations are possible until the cell has gone through mitosis.

It is not yet clear what specific qualities distinguish early firing origins from late firing ones. Clearly, differences in nucleotide sequence could affect the timing of one origin relative to another given the fact that key sequences bind the same regulatory proteins. Alternatively, the relative position of an origin to local chromatin structure and overall nuclear architecture might constrain initiation to mid- or late-S phase.

Archaea

Archaea, the third domain of life, can now be added as a model system for the study of regulatory mechanisms controlling DNA replication. Early studies indicate that although prokaryotic, the archaeal DNA replication machinery contains many attributes similar to those observed in eukaryotic cells. For example, although archaeal replication initiator proteins are not well conserved compared to other domains, they more closely resemble the origin recognition proteins (ORC) of eukaryotes rather than DnaA. Of great interest is the finding that some archaeal genomes, in *Sulfolobus* and haloarchaea, have circular chromosomes that contain multiple replication origins. Although these origins appear to fire synchronously, an initiator protein encoded by an origin-proximal gene regulates each origin independently. The regulatory mechanisms that control the timing of DNA synthesis from these origins are not yet known, although similarities to both bacterial and eukaryotic systems are reported. As more information becomes available, it will be interesting to examine the relationships among the different cell systems and determine the roles played by multiple origins on archaeal chromosomes.

Summary

As is the case for eukaryotes, many prokaryotes (eubacteria and archaea) are capable of triggering DNA synthesis from multiple replication origins, with each origin being restricted to firing only once per cell cycle. In this sense, the regulatory mechanisms governing initiation are fundamentally similar. The mechanisms are different in that yeast origins, unlike eubacterial origins, are not triggered synchronously. This finding suggests that eukaryotic origins exist in both easily triggered and delayed states. Thus, the initiation-triggering system in eukaryotic microbes must remain active for a considerable fraction of S phase. Under these circumstances, it is reasonable to suggest that the number of functional origins on eukaryotic chromosomes is dynamic, increasing or decreasing depending on developmental or physiological conditions that modify origin activity. These modifications may include changes in transcription activity and/or chromatin structure nearby or within origin regions.

Features of Microbial Replication Origins and Origin DNA-Protein Complexes

The primary function of replication origins is to provide regions where double-stranded DNA is easily unwound in response to cell growth-regulated signals. In microbes, these signals are mediated by multiple interactions of one or more specialized proteins with specific recognition sites within the replication origin. Ultimately, protein-DNA interactions produce an unwound DNA substrate suitable for the loading of DNA helicases followed by recruitment of a DNA polymerization machine to copy template strands. Once new replication forks are assembled, the initiation complex must be inactivated/disassembled and the origin reset for the next cell cycle. In all microbes studied thus far, persistent origin recognition protein complexes (ORC) serve as a scaffold for the cell cycle-specific assembly of pre-replicative complexes (pre-RC) that load DNA helicase.

Nucleotide Sequence Features of Replication Origins

What are the features of replication origins that distinguish them from other sites found on microbial genomes? This question is difficult to answer since nucleotide sequence alone does not always designate sites where DNA replication initiates. In *E. coli*, 245 bases are required (Fig. 2), but budding yeast (*S. cerevisiae*) origins vary in length from 100 to 200 bases, and up to 500–1500 bases are required for fission yeast (*Schizosaccharomyces pombe*) origins. However, there are some features that are common among all origins. For example, all microbial origins contain discrete modules that are highly A–T rich and can be easily unwound. These regions are termed DNA unwinding elements (DUEs). In *E. coli*, the DUE, located in the left half of the replication origin (Fig. 2), contains three tandem repeats of a 13 base sequence whose consensus is GATCTNTNTTTT. Unwinding of *oriC* is restricted to the 13-mer region, with primary unwinding in the rightmost 13-mer. Similar (A–T)-rich regions are found in other eubacteria and archaea, but there are no consistent rules regarding placement of the DUE within prokaryotic replication origins. In budding yeast, analysis of single-strand nuclease hypersensitivity and thermodynamic helical stability indicates the presence of DUEs in the B domain of ARSs (see below). However, there is no identified consensus sequence for yeast DUEs, and information from budding yeast does not extend to other yeast genera.

In addition to DUEs, all microbial origins contain recognition sites for origin-binding proteins. Prior to assembly of replication forks, specific origin-binding protein recognition sites must become occupied and oligomeric complexes must assemble at the correct time during the cell cycle (see below). All bacterial origins contain multiple 9-mer sequences with consensus 5'-TTATC/ACAC/AA-3'. These recognition sites, termed R boxes, have strong affinity for the initiator protein DnaA (see below). In *E. coli oriC*, three R boxes (R1, R2, and R4) are mapped (Fig. 2), but the arrangement and number of R boxes varies among bacterial types (up to 20 DnaA-binding sites are found in some bacterial genera). In many diverse bacterial types, including *E. coli*, *Caulobacter crescentus*,

Fig. 2 Structure of replication origins. (A) Schematic map of *oriC*, the *E. coli* replication origin. Relative locations of the consensus sequences for DnaA are shown. The high and low affinity sites (R1–R4, R5(M), C1), which bind DnaA–ATP and DnaA–ADP equivalently, are shown in dark and light blue, respectively. The sites that preferentially bind DnaA–ATP (I1–I3; C2–C3; τ 2), are shown in red. The DnaA–ATP sites in the 13-mer repeats, in the region where the origin unwinds (DUE), are shown by gray boxes. Fis and IHF binding sites are also indicated in yellow and green, respectively. The positions of the 13 GATC sites are marked by stars. The position of DNA-Trio sites are indicated by dark red rectangles to the left of R1. (B) Schematic map of *S. cerevisiae* ARS1. Relative locations of the A domain (blue) containing the ACS sequence, the B domains (red), and the DUE and ABF1-binding sites.

and *Mycobacterium tuberculosis*, DnaA does not bind all its recognition sites with equal affinity (K_d varies from ~ 1 to >50 nmol l^{-1} in *E. coli*) and this feature promotes the ordered assembly of initiation complexes.

Direct observation reveals that, in *E. coli*, DnaA occupies R1, R2, and R4 throughout the cell cycle and any further assembly of pre-RC must be due to low affinity DnaA interactions (see below). However, the occupation of all three sites is required to constrain *oriC* DNA and prevent spontaneous unwinding of the DUE. The ability to constrain is likely to require DNA looping to allow each of the bound DnaA molecules to interact with one another, presumably by Domain 1 interactions (see below). In recent studies, symmetrical arrays of four low affinity DnaA recognition sites were identified in each half of *E. coli* (Fig. 2). These 9-mer recognition sites (I boxes, Tau boxes and C boxes) differ from R box consensus sequence by three or more nucleotides and guide the assembly of DnaA oligomers along *oriC* DNA. Within each array, sites are separated from one another by two base-pairs, placing all the DnaA molecules on the same face of the helix. Each DnaA oligomer is nucleated from a peripheral high affinity R box (R4 and R1), but assembly is regulated so that the right oligomer precedes the left (see below). Unlike R boxes, which bind both the active form of DnaA (DnaA–ATP) and inactive DnaA–ADP with equal affinity, three of the low affinity sites in each array preferentially (fourfold) interact with DnaA–ATP. This binding preference is determined by the nucleotide sequence of these recognition sites and these sites couple pre-RC assembly to the availability of DnaA–ATP. However, mutant versions can be constructed which bind DnaA–ADP at all low affinity sites with equivalent affinity to DnaA–ATP. The DUEs of these versions can be unwound by DnaA–ADP and on chromosomes these origins are functional, but initiation of DNA synthesis is improperly regulated during the cell cycle. It appears that both forms of DnaA are functionally equivalent, but the predominant role of DnaA–ATP is in origin recognition and timing regulation.

Although less extensively studied than *E. coli*, other bacterial replication origins are also known to contain noncanonical DnaA binding sites. While the arrangement of the weak DnaA binding sites differs among bacterial types, low affinity sites tend to be located in the gap regions between high affinity DnaA sites. The number and spacing of weak sites also differs among bacteria, and may be tailored to organism-specific requirements for DnaA oligomerization. Since DnaA–ATP and DnaA–ADP are functionally equivalent in *E. coli* if both forms are permitted equal access to recognition sites, it is possible that DnaA–ADP makes a greater contribution to pre-RC assembly in some bacterial types and these differences are likely to contribute to *oriC* sequence diversity. Interestingly, all DnaA binding sites in origins of slow growing bacteria, such as *C. crescentus* and *H. pylori*, tend to have a lower affinity for DnaA than sites in origins of bacteria capable of rapid growth, such as *E. coli* or *B. subtilis*, suggesting either form of DnaA can be involved in pre-RC assembly.

Oligomers of DnaA–ATP also assemble along the single-stranded DNA of the unwound DUE, and these interactions are guided by distinctive DnaA-Trio motifs (3'-GAT-5', 3'-AAT-5', and 3'-GAA-5', Fig. 2) recently identified in a wide range of bacterial types. DnaA–ATP oligomers within the DUE are proposed to stabilize localized DNA unwinding and assist with helicase loading.

In budding yeast, an 11-bp ARS core sequence (ACS), 5'-A/TTTATA/GTTA/T-3', lies within a highly conserved and essential region called domain A (Fig. 2). The ACS binds ORC, a heterohexamer of Orc1–6 proteins, conserved in all eukaryotes (see below). In ARS1, ACS is not sufficient for origin function, and approximately 100 bp of 3' DNA is also required. This region is termed domain B (Fig. 2), and there is a great deal of sequence variability in this region among different ARSs isolated to date. The B domain is reported to carry the replication origin's DUE, and is further divided into essential subdomains (B1, B2, and B3), based on linker substitution mutagenesis. Domain B1, nearest to the ACS, is the most highly conserved. ORC binding extends over B1, based on in vivo footprinting experiments. B2 mutants are impaired for loading minichromosome-maintenance (MCM) proteins (see below), the presumptive replicative helicase in yeast. In addition, mutations in the B2 element reduce the frequency of origin firing. The B3 element binds the accessory protein ARS-binding factor (ABF1) (see below).

Although mapped in less detail, archaeal origins contain multiple conserved inverted repeat elements (about 36 bp) termed origin recognition boxes (ORBS) that are required for binding of the initiator Orc1/Cdc6. Smaller versions of ORB repeats termed mini-ORBS, perhaps analogous to the low-affinity initiator recognition sites in bacteria, were also mapped. Although the archaeal initiator proteins appear more related to the eukaryotic ORC proteins than to DnaA, assembly of multimeric complexes of Orc1/Cdc6 on archaeal origins is similar to the formation of DnaA complexes on bacterial *oriC*, mediating origin recognition, origin unwinding, and helicase loading. The presence of Orc1/Cdc6 binding sites of differing affinities (ORBS vs. mini-ORBS) suggests that staged initiator complex assembly is also required in at least some archaeal types to properly initiate DNA replication.

Common Properties of Origin Recognition Proteins

Origin recognition proteins from all domains of life are members of the AAA+ superfamily of ATPases. These proteins carry a nucleotide-binding domain that interacts with ATP and are able to hydrolyze the bound ATP to ADP. Conformational changes that accompany ATP hydrolysis produce a switch-like mechanism to activate and inactivate origin DNA–protein complexes (see below).

DnaA is the initiator in all known bacterial species, with DnaA from *E. coli* being the most extensively studied. DnaA is essential, and only conditional DnaA mutations have been isolated in any bacterial type. *E. coli* DnaA contains 467 amino acids, which are separated into four domains. Domain I is required for loading of DnaB, the replicative helicase, and also plays a role in DnaA oligomerization (a requirement for the assembly of functional pre-RC, see below). Domain II is a poorly conserved linker region. Domain III contains the motifs involved in ATP binding and hydrolysis, and is also required for DnaA oligomerization. DnaA associates with ATP immediately after synthesis and, in *E. coli*, levels of DnaA–ATP increase during the cell cycle prior to the onset of DNA synthesis. Following initiation in *E. coli*, DnaA–ATP is inactivated by a DNA replication-coupled mechanism termed regulatory inactivation of DnaA (RIDA, see below), in which the Hda protein stimulates the hydrolysis of ATP to ADP. Not all bacterial types contain an Hda homolog, and in some, intrinsic hydrolysis of DnaA–ATP is reported to be much faster than observed in *E. coli*, although the significance of this remains to be determined. Domain IV is responsible for DNA binding and possible interaction of DnaA with the cell membrane. In all known bacterial genera, Domains III and IV are highly conserved, and form what is known as the DnaA core. Structural analyses revealed that DnaA–ATP formed right-handed helical filaments capable of binding to, and stretching, single-stranded DNA. The *E. coli* helicase loader protein, DnaC, also binds to the end of the filament. Other forms of DnaA oligomers are also likely to exist, however, since Domain IV in the helical DnaA–ATP filament is folded back to make contact with residues in Domain III, and is not available for double-stranded DNA binding. The ability to assemble different complexes on single and double-stranded DNA could allow DnaA to promote origin unwinding as well as stabilize the unwound DUE as directed by the DnaA-Trio sequences.

In budding yeast, functional ORC is a heterohexamer of Orc1–6 proteins, with Orc1–5 being essential for site-specific DNA binding. Although five ORC subunits are reported to be AAA+ proteins capable of interacting with ATP, only the association of ATP with Orc1 is required to bind DNA, and binding to DNA inhibits the intrinsic ATPase activity of Orc1. Orc1, Orc4, and Cdc6 (see below) also carry a conserved winged-helix domain that is necessary for DNA binding, and perhaps is also used for protein–protein interactions within the ORC.

Although yeast ORC resides at origins throughout the cell cycle, some ORC subunits are specifically phosphorylated during the cell cycle by S-phase cyclin-dependent kinases. In addition, one ORC subunit may play a role in chromosome segregation. Orc6 associates with nuclear chromosomes during the cell cycle, but is reported to bind kinetochores during mitosis and promote cytokinesis (see below). ORC is reported to be limited in living *S. cerevisiae* (about one ORC complex per origin).

The AAA+ domains of eukaryotic Orc proteins and archaeal Orc1/Cdc6 are reported to contain conserved structural elements similar to those found in the DnaA core that may promote helical structure formation. In fact, a helical pentamer of DnaA can be docked within ORC at a position dominated by Orc5. This result suggests that helical structures may be a feature of all origin-recognition proteins.

Additional Proteins Associating With Bacterial and Yeast Origins

DnaA is not the only protein that associates with bacterial *oriC*. While the catalog of associated proteins is large and not conserved among all bacterial types, the associated proteins seem to use only a few common strategies to regulate formation of initiation complexes: modulation of low affinity DnaA binding, promoting or inhibiting DnaA oligomerization, and/or changing the conformation of *oriC*. In both *E. coli* and *H. pylori*, as well as other proteobacteria, DiaA/HobA promotes DnaA oligomerization and cooperative binding during initiation complex assembly. Interestingly, while loss of DiaA/HobA is tolerated in *E. coli* cells, it is required in *H. pylori*. The reason for this is not clear, but may be related to the generally reduced affinity of DnaA binding in *H. pylori*. Factors that associate with DnaA to reduce cooperative DnaA binding, such as YabA, DnaD, SirA, and Soj have also been identified in *B. subtilis*. Associated proteins that block DnaA's access to low affinity DnaA binding sites have been identified in *E. coli*, *C. crescentus*, *M. tuberculosis*, and *H. pylori*; these include SeqA (see below), CtrA, MtrA, and HP1021, respectively. Additionally, DNA bending proteins bind to replication origins of several bacterial types, changing the DNA conformation and modulating DnaA binding. For bacteria with bipartite origins, bending proteins may be needed to bring the two halves of the origin together, although further study is required to determine if this is the case. In *E. coli*, two histone-like bending proteins, integration host factor (IHF) and factor for inversion stimulation (Fis), specifically bind *oriC* (Fig. 2). IHF has also been shown to bind to the origins of other bacteria, including *C. crescentus*. In *E. coli*, Fis and IHF are not required for *oriC* function but appear to facilitate efficient synchronous assembly of the nucleoprotein complex that triggers initiation. IHF stimulates the binding of DnaA to low affinity recognition sites, while Fis inhibits such binding. It appears that conversion from a Fis-bound ORC to an IHF-bound pre-RC serves as a molecular switch to limit the time window required to trigger new rounds of DNA replication. Since Fis is also a growth rate-regulated protein with highest levels measured during rapid growth conditions, it remains to be determined whether this switch is required for initiation synchrony during rapid growth or whether the absence of Fis under slow growth conditions alters the assembly of the pre-RC.

For yeast ARS1, an accessory protein, ABF1, binds to the B3 subdomain. ABF1 is a multifunctional protein analogous to Fis or IHF in that it is involved in transcription regulation and is not absolutely required for either ORC binding or ARS function. Like IHF, ABF1 acts as an enhancer of origin function by producing changes in DNA conformation.

Prereplicative Complex (Pre-RC) Assembly in *E. coli* and Budding Yeast

The assembly of pre-RC is a dynamic, multistep process that is critically timed during the cell cycle. The process has been most extensively studied in *E. coli* and *S. cerevisiae*. In both of these organisms, ORCs, persisting throughout most of the cell cycle, are converted into pre-RC to license origins for DNA replication, and then reset to ORC after initiation (see below and Fig. 3).

In *E. coli*, *oriC* is bound to DnaA at only R1, R2, and R4 throughout the majority of the cell cycle, in a complex that is functionally and temporally analogous to yeast ORC. During rapid growth conditions, Fis is associated with the *E. coli* ORC and inhibits pre-RC assembly (Fig. 3). However, as new DnaA-ATP is synthesized during the cell cycle, it accumulates at *oriC* and three events, which result in pre-RC formation, can be measured: (1) Fis is displaced from its site; (2) IHF binds to its site between R1 and R2; and (3) IHF binding stimulates DnaA binding to the remaining lower affinity sites (Fig. 3). IHF binding and filling of the weaker DnaA sites forms the pre-RC, and results in origin unwinding in the DUE.

During unwinding, DnaA protein also interacts directly with the single-stranded 13-mer region in the DUE, and recruits DnaB–DnaC complex to the origin. The AAA+ protein DnaC is required to load the DnaB helicase hexamer (Fig. 3). DNA polymerase is then recruited to form the replication fork.

In budding yeast, a stable complex of Orc1–6 proteins and ABF1 binds to origins immediately after initiation, and remains bound throughout the cell cycle (Fig. 3). Formation of the pre-RC is accomplished during late mitosis/G1 and assembly of this complex licenses origins for helicase loading and new DNA synthesis. Licensing is possible only when cyclin-dependent kinase (CDK) activity is low, but high CDK activity is subsequently required to trigger movement of replication forks (see below).

A key step in converting ORC into pre-RC is the association of Cdc6, apparently via interaction with Orc1. Cdc6 is a highly conserved AAA+ protein with strong amino acid homology to Orc1. ORC and Cdc6 bind cooperatively to origin DNA and this binding is dependent on Orc1's ATPase activity. Cdc6 expression is cell cycle-regulated, with mRNA levels peaking at mitosis. Phosphorylation by CDKs causes rapid degradation of Cdc6 protein at G1/S transition. Temperature-sensitive *cdc6* mutant strains cannot progress to S phase at nonpermissive temperature, and overexpression of Cdc6 causes origin rereplication within a single cell cycle.

ATP hydrolysis by both ORC and Cdc6 is required to proceed with loading of an oligomeric ring-like complex of six different MCM proteins (Mcm2–7). MCMs are conserved among eukaryotes and each carries a 240 amino acid region similar to DNA-dependent ATPases. The MCM complex is the best candidate for the replicative helicase. A loading factor, Cdt1, forms a complex with Mcm2–7, and then this complex associates with ORC/Cdc6 (Fig. 3). Intracellular levels of both MCM proteins and Cdt1 are

Fig. 3 Multistep assembly of nucleoprotein complexes at replication origins. (A) Formation of pre-RC in *E. coli*. *E. coli oriC* is maintained throughout most of the cell cycle with DnaA (either nucleotide form; blue) bound to only R1, R2, and R4, with Fis binding adjacent to R2 in rapidly growing cells. Immediately before DNA replication initiates, the remaining, lower affinity sites are filled; this step requires DnaA-ATP (red) although R5M and C1 bind equally well to DnaA-ADP or DnaA-ATP. Additionally, Fis is displaced, and IHF binds between R1 and R5M. The DNA strands in the DUE then separate, and are stabilized by binding of DnaA-ATP in the DnaA-Trio region (shown in Fig. 2). Finally, DnaC loads DnaB onto the single-stranded DNA. (B) Formation of pre-RC in budding yeast. *ARS1* is bound throughout the cell cycle to ORC in the A domain, overlapping the B1 domain. ABF1 may bind the B3 domain as the pre-RC assembles. When CDK levels are low, Cdc6 is recruited to ORC. After Cdc6 binds, Cdt1 and MCM proteins are recruited, and MCM proteins are loaded onto the B2 domain, forming the pre-RC.

regulated so that these factors are only available in the nucleus during G1; they are retained in the cytoplasm during the remainder of the cell cycle. Surprisingly, multiple copies of Mcm2-7 are loaded at individual origins. The reason for this is unclear, but MCMs may be required at considerable distance from the origin, and the MCM complex moves with replication forks.

In yeast, loading of the MCMs completes pre-RC assembly, but several additional steps are required to convert Mcm2-7 in the pre-RC into an active DNA unwinding complex that allows cells to exit G1 and initiate DNA replication in S phase. These steps require high levels of CDK activity. First, a cell cycle-specific protein kinase, termed Cdc7-Dbf4, activates MCMs via phosphorylation. Second, additional factors must interact with phosphorylated MCMs; these include Cdc45, the GINS complex comprising four proteins (Sld5, Psf1, Psf2, and Psf3), and a complex termed 11-3-2 comprising Dpb11, Sld2, and Sld3. An S-specific CDK directly phosphorylates members of 11-3-2 prior to their association with MCMs and constitutes a key switch mechanism for the G1- to S-phase transition. The ultimate large complex of Cdc45-Mcm2-7-GINS, referred to as CMG, is the DNA-unwinding proficient version of the eukaryotic replicative helicase.

Limiting Initiation to Once per Cell Cycle and Replication Origin Resetting

Replication origins may be utilized once during each cell cycle, but never more than once. All cell systems studied thus far use multiple and redundant mechanisms to ensure the stringency of this rule. Most of these mechanisms focus on preventing reformation of the pre-RC. One way to do this is to regulate levels of proteins necessary to assemble pre-RCs; an example of this is degradation of Cdc6 at the G1/S transition. Another option is to modulate the activity of pre-RC proteins in a cell cycle-specific fashion. For example, once utilized, pre-RC proteins of the AAA+ family may be directly inactivated by ATP hydrolysis. Spurious reassembly of initiator complexes may also be prohibited by a variety of blocking agents. Finally, initiator proteins may be titrated away from origin sites by directing them to alternative DNA sites in prokaryotes, or exporting them from the nucleus in eukaryotes.

E. coli

To properly regulate timing of DNA synthesis, DnaA must be synthesized *de novo* each cell cycle. DNA replication begins when enough DnaA-ATP has accumulated to unwind the origin DNA and recruit the replication machinery. After replication forks begin their journey, rebinding of any remaining free DnaA-ATP to *oriC* must be prohibited to prevent reforming the pre-RC. At least three different mechanisms have been identified in *E. coli* to accomplish this goal (Fig. 4). First, hydrolysis of active DnaA-ATP to inactive DnaA-ADP is stimulated by a DNA replication-dependent mechanism termed RIDA. RIDA requires the β -subunit of DNA polymerase III holoenzyme complexed with a cofactor termed Hda. Presumably, any DnaA-ATP bound to DNA that contacts the replication fork during ongoing DNA replication will be inactivated. In particular, sites that bind large amount of DnaA (e.g. the *data* locus) may be “hot-spots” for DnaA-ATP inactivation. Hda is not widely conserved among bacterial genera, and in some bacteria, such as *B. subtilis*, the rate of spontaneous DnaA-ATP hydrolysis may remove the requirement for this protein. *B. subtilis* cells do contain factors that limit DnaA’s activity through means other than hydrolysis; one of these, YabA, associates with the β -clamp and limits cooperative DnaA binding by means that are not fully understood.

Although fork movement is probably responsible for the bulk of DnaA inactivation, it is unlikely that sufficient DnaA-ATP can be inactivated immediately after initiation to prevent reformation of the pre-RC. A second mechanism of downregulation involves blocking initiator protein access to *oriC*. In *E. coli*, *oriC* is blocked by a DNA-binding protein, SeqA, which recognizes and binds to hemimethylated GATC sequences, which are produced by replication of *oriC*. *E. coli*’s *oriC* contains 13 GATC sites (more than would be expected in a 245 bp region; see Fig. 2), and the placement of eight of these sites is conserved among enterobacterial origins. Normally, deoxyadenosine methyltransferase (Dam methylase) would fully methylate the palindromic hemimethylated GATC sequences shortly after they are formed. However, SeqA appears to “sequester” *oriC* from Dam methylase and other proteins,

Fig. 4 Regulation of pre-RC formation in *E. coli*. In *E. coli*, multiple mechanisms target low-affinity DnaA-binding sites to regulate formation of pre-RC before and after initiation. Before initiation, Fis, IHF, and DnaA-ATP regulate binding to low affinity sites to ensure proper initiation timing. After initiation, inactivation of DnaA-ATP by RIDA, blocking of weak sites by SeqA, and titration of DnaA by the *data* locus prevent reinitiation by inhibiting reformation of the pre-RC. Inactive DnaA-ADP is recharged to DnaA-ATP by interacting with DARS.

including DnaA, for approximately one-third of a generation. In this sequestered state, a new round of replication cannot be triggered. Mutant strains deficient in either SeqA or Dam methylase initiate more than one round of DNA replication per cell cycle. The GATC binding sites for SeqA overlap several lower affinity DnaA binding sites (Fig. 4). By targeting only the weak sites, SeqA specifically blocks pre-RC assembly, but permits DnaA loading at strong sites R1, R2, and R4 to reset the origin immediately after initiation. While SeqA is not a conserved protein, other bacterial types use a similar blocking strategy to inhibit initiations. In *Caulobacter* species, the global regulator CtrA binds to *oriC* and blocks at least one key DnaA binding site. In *M. tuberculosis*, the inhibitory protein MtrA also binds to *oriC* in regions that overlap DnaA recognition sites.

The third mechanism to downregulate pre-RC reformation depends on the duplication of a high-capacity DnaA titration site downstream from *oriC*. This site, termed *datA*, is reported to bind as many as 370 molecules of DnaA. Consequently, duplication of *datA*, approximately 8 min after DNA synthesis initiation, provides a cell cycle-specific mechanism to reduce the availability of DnaA during the sequestration period, so that there is not enough free DnaA to reassemble pre-RC when *oriC* loses its SeqA blocker (Fig. 4). *DatA* also likely provides a reservoir of DnaA for inactivation by RIDA.

Upregulation also exists. Under fast growth conditions where sufficient DnaA-ATP may not be synthesized de novo, *E. coli* is able to reactivate DnaA-ADP to active DnaA-ATP. The reactivation mechanism is based on specific nucleotide sequence motifs termed DnaA Reactivating Sequences (DARS) located at two different sites on the genome (DARS1 and DARS2 (Fig. 4). Although the exact mechanism for reactivation remains obscure, DARS both carry three DnaA recognition sites. The activity of DARS2 requires the interaction of DNA bending proteins Fis and IHF, suggesting that a specific DNA conformation is required for the reactivation of DARS-bound DnaA.

Yeast

In yeast, pre-RC formation must also be prohibited following the onset of S phase during each cell cycle. Since the eukaryotic cell cycle is driven by fluctuations in the levels of cyclins, it is not surprising that CDKs and their regulator, anaphase-promoting complex (APC), play key roles in restricting origin-firing to once and only once per cycle. Multiple CDK-regulated mechanisms act on the components of pre-RC, analogous to multiple mechanisms reducing pre-RC formation in prokaryotes. For example, Orc2 is directly phosphorylated by CDKs in late G1, S, G2, and M phases to inhibit its activity. Additionally, association of Cdc6 with Orc1 absolutely depends on low CDK activity, since phosphorylation, triggered by a rise in CDK levels at the end of G1, targets Cdc6 for degradation by ubiquitin-mediated proteolysis. Transcription of new Cdc6 is also reduced by CDK activity. The combination of reduced transcription and proteolysis results in Cdc6 levels that are insufficient to form the pre-RC. Other components of pre-RC are also targeted after initiation to prevent origin licensing. Mcm2-7, associated with Cdt1, normally enters the nucleus at the end of mitosis and remains in this location during G1. At the G1/S interface, rising CDK-dependent phosphorylation targets MCMs and Cdt1 for nuclear export, making them unavailable to reform active pre-RC.

All CDK-dependent inhibitions of origin licensing are eliminated by the increase in APC from late mitosis through early G1. APC is a ubiquitin ligase that begins the process of CDK proteolysis. After the formation of pre-RC, APC is inactivated to allow CDK levels to again rise, so that a new round of DNA synthesis can begin.

Summary

Both prokaryotic and eukaryotic microbes control initiation of chromosome replication by multistep, ordered assembly of a nucleoprotein complex at an origin of replication. Reinitiation is prevented by mechanisms that inhibit reformation of the pre-RC. In bacteria, the rate at which the initiator protein DnaA accumulates at the origin determines the frequency of initiation, and cell cycle-specific expression of *oriC*-binding proteins is not necessary for proper initiation timing. Inactivation of DnaA, blocking of DnaA binding sites to prevent pre-RC reassembly, and titration of DnaA away from *oriC*, prohibit reinitiation events in the critical time following origin firing. In contrast, yeast cells contain cell cycle-specific kinases that regulate all aspects of origin function, such that key components are present and/or functional during a discrete time period of the cell cycle. The processes of initiation, chromosome replication, and segregation are separated temporally, and this separation is governed by a series of molecular checkpoints. With such a sophisticated regulatory network in place, it is not surprising that the yeast cell rarely commits an error. In fast-growing *E. coli*, DNA replication and segregation are ongoing when new rounds of replication initiate from *oriC*. If bacteria are to maintain the survival advantages resulting from rapid growth, they apparently cannot afford the luxury of restricting times that DNA may replicate during the cell cycle. Instead, bacterial cells have evolved regulatory mechanisms that are coupled to DNA replication but not to any other specific events during the cell cycle including cell division. Although this form of regulation is more streamlined than that found in eukaryotic microbes, it is no less precise.

Chromosome Segregation Systems in Prokaryotic and Eukaryotic Microbes

After successfully replicating their genomes, microbes must ensure that each new daughter cell receives the correct complement of chromosomes after cell division. Mechanistically, this is not a trivial process and there are obviously many steps where errors could lead to the production of nonviable cells. A successful segregation system requires several components: (1) a mechanism to identify the location of each nascent daughter chromosome, (2) a means for physical attachment to chromosome copies, and (3) a polarized

motor activity to pull chromosome copies into separate physical spaces destined to become new cells. During mitosis in eukaryotic microbes, structures for physical separation of chromosomes, the spindle pole bodies (SPB), are visible with the aid of a microscope. The vehicle for segregation is not so obvious in bacteria. Bacteria contain few visible intracellular structures and, until recently, there has been no evidence of centromeres (see below); little information on intracellular organization of segregating chromosomes is available. In addition, the segregation mechanism in bacteria must, under rapid growth conditions, be functional while DNA replication is ongoing. Because of these clear differences, it was expected that bacteria and yeast would segregate their chromosomes via markedly different mechanisms. However, there is now evidence that active mechanisms exist to precisely localize replication origins and distribute newly replicated genetic loci in bacteria. Current data suggest that in some ways, eukaryotic and bacterial microbes use similar strategies to segregate chromosomes. Furthermore, studies on bacterial chromosome segregation clearly show that profound spatial organization of the genome and mechanisms must exist to maintain this organization during a progressive segregation process.

Segregating Chromosomes in Budding Yeast

Prior to the onset of chromosome replication, specialized proteins, called cohesins, are loaded onto yeast chromosomes. After S phase, these cohesins pair and hold together the newly replicated sister chromatids (Fig. 5). Then, as cells enter mitosis, the yeast chromosomes are condensed by the action of a variety of proteins, including the condensin complexes, which makes the chromosomes more rigid and compact. The condensation process requires factors associated with the centromere. In mitosis, the kinetochores of the paired, compact chromosomes attach to the spindle, comprising interdigitated microtubules emanating from the SPB. This process is regulated to ensure that there is bipolar (amphitelic) attachment of microtubules to each sister chromatid's kinetochore. This amphitelic attachments cause tension between the sister chromatids, as kinetochore motor proteins try to separate the attached chromosomes. As the cells enter anaphase, the cohesins holding sister chromatids together are synchronously dissolved, allowing the motor proteins to segregate the chromosomes to opposite poles. Although this scenario seems simple, the molecular machinery of segregation in yeast is complex. It must include protein–DNA interactions that control cohesion and condensation of sister chromatids, as well as the assembly of a multicomponent DNA–protein structure, termed the kinetochore, that associates microtubules and motor proteins with centromere DNA. Failure to assemble or disassemble these components of the segregation system results in cell cycle arrest.

The linkage of sister chromatids by cohesins is beneficial, since it obviates the need to localize each sister chromatid individually before bipolar attachment to spindle microtubules. Initially, the replication process generates intertwining of DNA and produces physical linkage of sister chromatids. These DNA catenanes are removed by DNA topoisomerase II, which is part of the condensed

Fig. 5 Separation of sister chromatids in yeast. After chromosomes (blue) are replicated, they are paired by cohesion complexes (red). Kinetochore (green) assemble at the centromeres (yellow) of the sister chromatids. Microtubules emanating from the SPB bind to the kinetochore. Cohesion is maintained until both the kinetochores of sister chromatids are attached to separate microtubules. Then, APC ubiquitinates securin (rust triangle), triggering it for degradation and releasing separase (brown). Separase cleaves the cohesion complex, and the sister chromosomes are separated by motor protein activity associated with the kinetochores and microtubules.

chromosome scaffold. However, the cohesins, loaded prior to chromosome replication, ensure that sister chromatids do not separate until anaphase.

In *S. cerevisiae*, a cohesion complex comprises four proteins: Smc1, Smc3, Scc1/Mcd1, and Scc3. SMC (structural maintenance of chromosomes) proteins are conserved among some bacteria and most eukaryotes, including humans. Smc1 and Smc3 carry hinge and long-coiled coil regions that assemble into a V-shaped heterodimer with an ATP-binding motif. The V-shaped heterodimer is closed into a ring by the specific binding of Scc proteins to the globular heads of the Smc proteins. Once assembled, the cohesion complexes are loaded onto chromosomes with the assistance of Scc2 and Scc4 and the passage of the replication fork. Loading requires an ATPase activity associated with Smcs. The nucleosome remodeling mechanism in yeast is also involved since RSC (Remodels the Structure of Chromatin complex) recruits Scc2-Scc4 to nucleosome-free regions of the chromosome. Cohesion is maintained until anaphase begins, and this allows sufficient time for the kinetochore to be attached to the spindle (Fig. 5).

Kinetochore assemble via specific protein–DNA interactions at centromeres. The centromeres of *S. cerevisiae* chromosomes are quite small (120 bp) relative to other eukaryotic centromeres (which are contained in megabase domains of repetitive DNA). The *S. cerevisiae* centromere consists of three nucleotide sequence elements, termed CDEI, CDEII, and CDEIII. CDEI is an 8 bp sequence conserved among all yeast chromosomes. CDEII is a 78–86 bp, >90% (A–T)-rich sequence that separates CDEI and CDEIII. CDEIII is a conserved 24 bp sequence. CDEI and CDEIII are essential for chromosome segregation, since deletion of CDEI increases chromosome loss 10-fold and deletion or point mutations of CDEIII destroy centromere function.

In contrast to the centromere sequence, centromere-binding proteins of *S. cerevisiae* show little similarity to analogous proteins in other yeasts and higher eukaryotes. However, in all cases, kinetochores are large protein assemblies. In *S. cerevisiae*, kinetochores comprise 60 different subunits arranged in layers as 14 discernable complexes. A four-protein inner complex, termed Cbf3, binds specifically to CDEIII and is key for initiating kinetochore assembly. After binding to CDEIII, one of the Cbf3 proteins, p58, is activated by phosphorylation and later degraded by ubiquitin-mediated proteolysis. By this mechanism, assembly of the kinetochore can be limited to one per chromatid and assembly can be restricted to a limited time during the cell cycle.

The kinetochore links spindle microtubules to sister chromatids (Fig. 5). The spindle microtubules emanate from the SPB, which is embedded in the nuclear membrane throughout the cell cycle. Duplication of the SPB takes place prior to the onset of S phase in *S. cerevisiae*, and is facilitated by RSC-dependent distribution of nuclear membrane insertion factors Nbp1 and Nde1 to each new SPB. Surprisingly, the spindle (SPB with microtubules) first appears during S phase in budding yeast, suggesting that chromosome replication and spindle assembly comprise two separate regulatory pathways. Spindle elongation and subsequent chromatid separation requires kinesin-related proteins Kip1 and Cin8 and a dynein-related protein Dyn1 to provide both pushing and pulling forces. There is also evidence for mechanochemical motor activity associated with the kinetochore.

In budding yeast, each kinetochore captures only one independent microtubule. A mechanism to detect improperly oriented attachments exists, and is dependent on the ability of proteins in the kinetochore to sense tension generated by the action of motor proteins trying to separate chromosomes held together by cohesins. Attempts to reattach are continued until the correct orientation is achieved. It is likely that only one of the sister chromatids initially becomes attached to a spindle microtubule. The attachment, however, causes the movement of both chromatids, which oscillate as the microtubule grows and shrinks. This oscillation may prevent the remaining kinetochore from attaching to other microtubules from the same SPB. Only binding of the remaining kinetochore to a microtubule from the opposite SPB can produce the bidirectional force required to trigger dissolution of cohesions holding the chromatids together (Fig. 5). Since the release of cohesion during the cell cycle is such a dramatic event, there are several checkpoint proteins complexed with the kinetochore to monitor the events in early mitosis and inhibit chromosome segregation until all chromatids are properly attached to microtubules.

The loss of cohesion is synchronous and very tightly regulated. Scc1 is cleaved by a cysteine protease termed separase (Esp1), whose activity is held in check by a chaperone protein called securin. Securin is degraded by APC to release active separase only in anaphase (Fig. 5). When Scc1 is cleaved, the linkage holding the sister chromatids together is broken, and the chromosomes are segregated by the motor forces in the microtubules and kinetochore.

Origin Localization and Chromosome Segregation in Prokaryotes

Little obvious structural organization within the cytoplasm of prokaryotes has been observed in *E. coli* or any other eubacteria, and there is certainly no structure equivalent to the mitotic spindle segregation system. However, bacterial cells must have a highly effective equipartitioning system to segregate sister chromosomes, since anucleate cells are rarely produced. This perplexing situation resulted in models that included the cell surface as part of the segregation machinery. The 1963 Replicon hypothesis proposed by Jacob, Brenner, and Cuzin suggested that the replication origin could act as centromere, and the sites at which the origin attached to the membrane could function as an SPB (centrosome) in *E. coli*. Although the physical force separating bacterial chromosomes has yet to be identified, it is clear that bacteria contain mechanisms to accurately relocate newly replicated chromosomal origins to specific intracellular sites followed by ordered, progressive segregation of duplicated loci in a way that maintains the orientation of segregated chromosomes into newly divided daughters (Fig. 6).

Most information on the intracellular position and movement of genomic loci has come from *E. coli*, *B. subtilis*, and *C. crescentus*, using several elegant methods. One approach, termed fluorescent repressor operator system (FROS), involves inserting DNA cassettes containing multiple copies of the *lac* operator into the chromosome at the genetic location to be tracked. Time lapse microscopy then follows the intracellular location of green fluorescent protein (GFP) linked to Lac repressor, which binds to the cassettes. An alternate approach is fluorescence in situ hybridization (FISH), in which fluorescently labeled DNA probes for specific

Fig. 6 Localization of *oriC* during the cell cycle. Schematic diagram of the localization of *oriC* in *E. coli* or *B. subtilis* during the cell cycle. *OriC* is at mid-cell in newly divided cells, and remains there until DNA replication initiation. After duplication of *oriC*, the two origins are actively relocated to positions that are one-fourth and three-fourth the length of the cell. As the chromosome is replicated, the sister chromosomes are also separated into each half of the cell. After cell division, each daughter cell has a complete chromosome, and *oriC* is again located at mid-cell.

loci are hybridized to fixed cells on microscope slides. Partition proteins have also been localized during the cell cycle using fluorescent antibodies as in situ probes.

Bacterial replication origins are positioned at specific cellular locations prior to the onset of DNA synthesis (polar in *C. crescentus* and near mid-cell in *E. coli* and *B. subtilis*; see Fig. 6). How the correct placement of *oriC* is achieved in most bacteria remains to be determined, but it is likely that the origin localization mechanisms will vary depending on cell shape and life style. After DNA synthesis initiates, duplicated origins are actively separated to the one-fourth and three-fourth cell position in *E. coli* and *B. subtilis* (Fig. 6) or to opposite poles in *C. crescentus*. There have been various proposals to explain how the force acting on replication origins is generated; it has been suggested to be derived from the replication process itself, by a mechanism related to transcription, to the synthesis of membrane components between newly replicated origins, or by a dynamic change in nucleoid structure (see below). While none of these mechanisms can be ruled out and perhaps several will act cooperatively, origin translocation across cellular space is unusually rapid, raising intriguing issues about the existence of kinetochore-like components that specifically act on origin regions to determine their position in cells and move them apart during the replication process.

Several candidate components of a bacterial kinetochore are described in the most widely studied bacterial systems. Two related systems were uncovered in sporulating *B. subtilis*. During sporulation, an origin-localizing protein, RacA, targets *oriC* to cell poles after binding preferentially to 25 regions spread over 612 kb across the origin portion of the chromosome. RacA has the ability to condense chromosomal DNA. *B. subtilis* also contains chromosomally encoded proteins that are similar to members of the Par family, partition proteins encoded by plasmids. Most plasmid systems encode two interacting Par proteins (ParA, B) and carry a *cis*-acting centromere-like element (*parS*). In most plasmid systems, ParA is an ATPase, and ParB binds directly to *parS*. In *B. subtilis*, Spo0J is a homolog of the plasmid-partitioning protein ParB, binding to at least eight sites spread over 800 kb in the *B. subtilis* *oriC* proximal region. Loss of Spo0J leads to 100-fold increase in anucleate cells. Spo0J also plays a role in origin positioning in the forespore, suggesting redundancy in *B. subtilis* kinetochore systems. Par family proteins also exist in *C. crescentus*, with a role in preventing anucleate cells, but an actin-like protein called MreB is thought to direct origin movement, without affecting other chromosomal loci. MreB appears to associate directly with origin proximal DNA and forms a spiral corkscrew on the cell surface that could serve as a track for origin movement. MreB is also present in *E. coli* and *B. subtilis* where it has been implicated in determining cell shape as well as playing a role in chromosome segregation. Additional candidate components include the bacterial members of the SMC family of proteins. Mutations in the *smc* genes of *B. subtilis* and the SMC-like Muk complex (encoded by *mukB*, *E*, and *F*) in *E. coli* produce less condensed nucleoids and anucleate cells. These complexes are expected to play a role in chromosome compaction, but it was recently shown that in both bacterial types the SMC proteins are also responsible for correctly separating and positioning new *oriC* copies.

It remains unclear whether the forces responsible for separating origins are also responsible for segregating the bulk of chromosomal DNA. Perhaps the moving force is found in the nucleoid itself. All recent studies show clearly that the nucleoid is well organized and exhibits a highly regulated spatial location in cells during replication and partitioning of daughter chromosomes. Based on studies in *C. crescentus* and *E. coli*, replication divides the circular genome into two distinct and equal arms termed replicores that occupy separate halves of the cells. This spatial orientation is maintained generation after generation by the sequential layering of newly replicated DNA to the inner and outer edges of developing nucleoids. Recent studies clearly show that the nucleoid is a remarkably dynamic structure undergoing rapid fluctuations in density, and several abrupt global reorganizations. These mechanical changes may be sufficient to drive nucleoids apart during the cell cycle without the need for any

additional motors. If this is correct, perhaps the segregation mechanism will only require guiding proteins, like those described above, to orient the DNA as it is replicated.

Glossary

Constant light (LL) A condition where organisms are held in continuous light, i.e. no dark period is given to the cells. After entrainment, cyanobacterial cells are released into LL to observe the free-running rhythm.

Diazotrophic Refers to organisms that are capable of fixing atmospheric nitrogen into ammonia.

Diel Cycle A 24-h period consisting of alternating light (day) and dark (night) conditions.

Entrainment A property of circadian rhythms in which the clock can be reset by external cues, thus establishing a particular phase relationship with the external environment. In typical experimental conditions we entrain the samples to an LD 12:12 cycle so that peak expression of reporter genes occurs at a particular time, dusk or dawn, relative to the provided LD cycle.

Free-running period (FRP) The periodicity of the rhythm in constant conditions. The typical FRP is approximately, but not exactly, 24-h.

Hourglass timer A timing system that once triggered can execute a temporal program. However, the program does not persist in constant conditions and cannot reinitiate a new cycle without environmental input.

Light-Dark (LD) Environmental cycle consisting of alternating periods of light and dark. LD 12:12, also referred to as a diel cycle, would indicate having the lights on for 12 h followed by 12 h in darkness.

Persistence A property of circadian rhythms meaning that the rhythm continues in the absence of environmental cues. Persistence is often demonstrated by placing organisms in either constant light or constant dark conditions and monitoring for sustained rhythmicity.

Temperature compensation A property of circadian rhythms in which the periodicity of the circadian clock remains ~24-h over a range of biological temperatures. In contrast to most enzymatic activities, for which reaction rates increase 2–3 fold with a 10°C increase in temperature, the circadian clock is buffered or compensated against changes in temperature that occur over the course of the day, and shows less than 10% change in period over that range.

Transcription-translation feedback loops (TTFL) A negative feedback loop in which genes code for proteins that, directly or indirectly, feed back to inhibit their own expression. Once protein levels have dropped through degradation, repression is relieved and the cycle begins again as the factor's gene can be transcribed and its message translated until the factor accumulates enough to repress its own expression. Post-translational modification and proteolysis contribute to these timing loops.

Ultradian rhythm A recurrent rhythm that has periodicity of less than a 24-h cycle. For example, rhythms that have a periodicity of 2 h, 4 h, 6 h, 8 h and 12 h would all be considered ultradian, as would very fast rhythms such as heartbeats in humans.

Fundamental Properties of Circadian Rhythms

Organisms growing in a changing environment use many methods to synchronize with their surroundings. One such mechanism that is very wide-spread in nature is a biological clock, driven by an oscillator. 24-h biological clocks that drive circadian rhythms, oscillations in biological activity that peak approximately once per day, are crucial for many organisms to coordinate biological activity over the course of the day. Evidence for circadian rhythmicity can be found everywhere; all one has to do is look. As early as 1729, Jean-Jacques d'Ortous de Maribus reported that the daily opening and closing of the leaves of the mimosa plant persists in constant darkness, that is, in the absence of a *light-dark* (LD) cycle. This early experiment provided a hint that this process was not occurring in response to the rising and setting of the sun, but rather that the mimosa plant had an internal timing system independent of the external conditions. However, de Maribus himself was hesitant to draw such conclusions, as he was not able to rule out other external factors such as temperature or gravity. Proving the existence of a circadian clock that could anticipate, rather than respond to, daily changes in our environment, was a challenging scientific problem that was settled only centuries later.

Circadian rhythms can be found ubiquitously throughout nature and are studied extensively in model systems that span the tree of life, including bacteria, fungi, plants, flies, mice, and humans. Although prokaryotic cells were originally thought not to be complex enough to support – or have need for – a circadian clock, we now know that circadian rhythms are indeed a property of some prokaryotes. While cyanobacteria are currently the only known prokaryotes to possess a *bona fide*, robust circadian clock that runs in continuous conditions, 24-h rhythmicity in a *diel* cyclic environment is pervasive throughout the prokaryotic world. New reports have suggested the existence of prokaryotic circadian clocks outside of cyanobacteria, as well as 24-h oscillations in

Fig. 1 Fundamental principles of entrainment, persistence and temperature compensation. (A) Bioluminescence (y-axis) measured from an *S. elongatus* reporter strain, *P_{kaiBC}-luciferase*, for two days in LD 12:12 and three days after release into constant light conditions (LL). Rhythms of gene expression persist even in the absence of a light-dark cycle. Moreover, the phase of the oscillation remains the same in LL, demonstrating that the phase was entrained to the preceding LD cycle. (B) Graphical representation of temperature compensation. The period of the circadian rhythm as monitored from a luciferase reporter (y-axis) plotted as a function of temperature (x-axis) shows that the period varies no more than 10% over a 10-degree range of biologically relevant temperatures. Original data from Kondo, T., Strayer, C.A., Kulkarni, R.D., *et al.*, 1993. Circadian rhythms in prokaryotes: Luciferase as a reporter of circadian gene expression in cyanobacteria. *Proc. Natl. Acad. Sci. USA* 90 (12), 5672–5676.

biological activity from organisms that don't have a circadian clock but may instead respond to a cue(s) from circadian organisms in the same community.

While the mechanism of the prokaryotic oscillator is different from that in eukaryotic models, they share a remarkable number of properties, including the three fundamental hallmarks of circadian rhythms: *persistence*, *entrainment* and *temperature compensation* (Fig. 1). Circadian rhythms are defined by the ability to persist in constant conditions, meaning the ~24-h oscillation will continue in the absence of environmental cues, i.e., in *constant light* (LL) or constant dark conditions, demonstrating that circadian rhythms are not driven by the environment but rather are endogenous and genetically programmed. The periodicity of the rhythm in constant conditions is referred to as the *free-running period* (FRP). The typical FRP is approximately, but not exactly, 24-h. The second criterion of circadian rhythmicity is the capacity for entrainment, meaning that the clock can be reset by external cues, thus establishing a particular phase in relationship to the external environment. In the natural world, circadian oscillators all need to adjust slightly in order to synchronize with the 24-h environmental cycle, as the FRP of the organism is not exactly 24-h. However, when the environment is changed more drastically, e.g., a time zone change, the circadian clock takes longer to synchronize with the surroundings, resulting in jet lag. Finally, circadian clocks are temperature compensated, meaning that they maintain a periodicity of ~24-h over a range of biologically relevant temperatures. In contrast to most enzymatic activities, for which reaction rates increase with temperature, the ticking of the circadian clock is buffered or compensated against changes in temperature that occur over the course of the day.

By definition, circadian clocks enable the anticipation of daily environmental changes, so that the organism is prepared for the rising and setting of the sun. This strategy is in contrast to the function of an *hourglass timer* that is set in motion by a change in the environment and would need a new stimulus every day. In addition to summarizing the current status of the prokaryotic circadian clock, we will provide examples of organisms with hourglass timers, which do not persist in constant conditions, and discuss how these two types of clocks may function to contribute to rhythms in complex environments.

Clocks in Prokaryotes

Even before the discovery of circadian clocks in prokaryotes, ~24-h rhythms of photosynthesis and nitrogen fixation that hinted at their existence were reported in several *diazotrophic* genera of cyanobacteria. At the time, prokaryotes were thought to be too simple to have a circadian clock; thus, these rhythms were always attributed to regulation dependent on the external environment or a consequence of the cell cycle. Experiments to test whether these daily rhythms fulfilled the criteria for circadian rhythmicity were not performed until 1986, when Huang and colleagues demonstrated that the rhythms of nitrogen fixation and amino acid uptake in *Synechococcus* sp. RF-1 satisfied the three criteria accepted by the scientific community to be requirements of a *bona fide* circadian rhythm: persistence, entrainment and temperature compensation. For further genetic analysis of the cyanobacterial circadian clock, however, two things were required: an organism amenable to genetic manipulation, and an easy and robust reporter system. In 1993, a joint effort by the laboratories of Takao Kondo, Carl Johnson and Susan Golden, reported the use of luciferase to monitor circadian rhythms of gene expression in *Synechococcus elongatus* PCC 7942. Today, the genetically tractable *S. elongatus* serves as the paradigm for prokaryotic circadian rhythms. Work in this elegant

system has led not only to an understanding of the genetics that underlie the prokaryotic circadian clock, but also to an atomic resolution of its structure and function.

S. elongatus as a Model for Prokaryotic Circadian Rhythms

In *S. elongatus* the KaiA, KaiB and KaiC proteins compose the core or central oscillator required to keep 24-h time. Unlike the transcription-translation feedback loops (TTFL) that typically form the basis of eukaryotic circadian oscillators, the Kai proteins function as a post-translational oscillator where associations with KaiA and KaiB drive 24-h rhythms of KaiC phosphorylation. KaiC is an auto kinase, auto phosphatase and ATPase, comprising two domains (CI and CII) that come together to form a hexameric structure that looks like two rings stacked on top of each other (Fig. 2). During the day KaiA promotes KaiC autophosphorylation by binding to the A-loops, flexible C-terminal extensions on KaiC, promoting a conformation of KaiC that favors the autokinase activity (Fig. 2(B)). KaiC phosphorylates itself first on Threonine 432 (KaiC-SpT), followed by phosphorylation of Serine 431 (KaiC-pSpT), both present in the CII domain of KaiC. Phosphorylation makes the KaiC domains rigid and increases interaction between the rings. When KaiC is in its fully phosphorylated form, the interactions between the CI and CII domains of KaiC become so rigid that the CII stacks tightly on the CI ring. Stacking exposes the B-loops, or the binding site for KaiB in the CI domain of KaiC. KaiB associates with KaiC via an interaction with the B-loops as well as with KaiA, sequestering KaiA away from the A-loops and forming the nighttime KaiABC complex. The form of KaiA that is captured by KaiB is an inactive state. By sequestering KaiA away from the A-loops, KaiB promotes the auto-dephosphorylation of KaiC during the nighttime portion of the cycle, during which KaiC will first remove the phosphoryl group from the Threonine, followed by dephosphorylation of the Serine, returning KaiC to its original non-phosphorylated state (Fig. 2(B)). Rhythms of KaiC phosphorylation that are temperature compensated and have a periodicity of ~24-h can be reconstituted *in vitro*, confirming that the KaiABC proteins are sufficient to drive 24-h rhythms in cyanobacteria. More recent structural investigations of the KaiABC complex, discussed in more detail below, have revealed several fundamental mechanistic insights into the function of the oscillator.

While the KaiABC oscillator can run in isolation *in vitro*, the oscillator within the cell needs to be able to synchronize with the environment and relay time to clock-controlled activities. The core oscillator synchronizes with the environment both directly and indirectly via proteins that monitor cellular redox. CikA, Circadian Input Kinase A, is a critical component of the extended oscillator

Fig. 2. Model of the *S. elongatus* core oscillator. (A) Cartoon representations of the KaiA dimer, KaiB in the fold-switched monomeric state, and the KaiC hexamer. Phosphorylation sites Serine 431 and Threonine 432 reside in the CII ring of KaiC. (B) At dawn KaiC starts off in a non-phosphorylated state, with CI and CII rings loosely stacked. KaiA binds to the A-loops of KaiC, promoting KaiC autophosphorylation during the day. Red circles represent phosphorylation events. Once KaiC is fully phosphorylated the CI and CII rings stack such that the B-loops on the CI ring become exposed. KaiB, once bound to KaiC, can sequester KaiA in an autoinhibited conformation, promoting KaiC autophosphatase activity during the night. Graphics courtesy of the UC San Diego Bio Clock Studio.

that plays roles both in input to and output from the clock, and affects circadian period. Strains that lack *cikA* display a variety of circadian phenotypes including short period, low amplitude rhythms of gene expression, and most strikingly, a failure to reset the phase of the oscillator by several hours in response to a dark pulse, a feat executed efficiently by WT. CikA plays critical roles in synchronizing and resetting the oscillator with the environment via its ability to interact with quinones, whose redox status varies as a function of photosynthetic activity. Specifically, CikA as well as core oscillator protein KaiA, directly bind to the oxidized form of quinone, an indicator of the onset of nighttime. Moreover, the addition of oxidized quinone can reset the oscillator both in *in vitro* and *in vivo*, suggesting that the redox status of the quinone pool is critical for relaying environmental signals to the oscillator. Even though a $\Delta cikA$ mutant does not reset the phase of the oscillator in response to a sudden dark pulse, the strain shows a coherent rhythm after entrainment to 2 LD cycles, suggesting that there is more to the story of environmental synchronization. Indeed, LdpA, an Fe-S binding protein, plays a role in aligning the clock with the environment by fine-tuning the circadian period in a light-intensity dependent manner, potentially via regulating CikA protein levels. Additionally, KaiC itself is sensitive to the [ATP/ADP] ratio in the cell, which declines slowly during the nighttime portion of the daily cycle; indeed, altering the [ATP/ADP] ratio can reset the oscillator *in vitro*. The current model to explain how the oscillator becomes entrained with the environment is that the oxidation state of the quinone pool, which becomes rapidly oxidized upon the change to dark, signals the onset of the nighttime period, while the slow change in the [ATP/ADP] ratio in the cell reports the duration of the night. Together, these cues allow the core oscillator to know when night has begun and how long the night persists, enabling the oscillator to synchronize with the external environment.

The oscillator requires a mechanism of circadian output to coordinate biological activity over the course of the day. CikA, SasA and RpaA are the key players that enable the oscillator to transmit temporal information to clock-controlled behaviors (Fig. 3(A)). Briefly, association with the Kai complex at different times during the cycle activates the kinase or phosphatase activity, respectively, of two regulators of a master transcription factor, RpaA (Fig. 3(A)). SasA is a histidine kinase that becomes activated via an association with KaiC to phosphorylate itself and transfer that phosphoryl group to its cognate response regulator, RpaA. SasA associates with KaiC during the day, thus increasing [RpaA-P/RpaA] (Fig. 3(B)). CikA, in addition to its known roles in relaying environmental information to the oscillator, dually functions in relaying information from the oscillator by acting as a phosphatase towards RpaA. This phosphatase activity is stimulated by CikA association with KaiB after formation of the KaiC-KaiB complex, with CikA likely competing with KaiA for KaiB binding (Fig. 3(B)). While SasA phosphorylates RpaA during the day, CikA dephosphorylates RpaA at night, resulting in a 24-h rhythm of RpaA-P, with RpaA-P levels peaking at dusk (Fig. 3(B)). The regulation of SasA and CikA functions are discussed in more detail below.

RpaA is a DNA-binding transcription factor that, in its active phosphorylated state, activates the expression of dusk-peaking genes and represses the expression of dawn-peaking genes. The deletion of *rpaA* eliminates genome-wide rhythms of gene

Fig. 3. Model of the *S. elongatus* output pathway. (A) Cartoon structures of output components SasA with N-terminal KaiC-interacting domain and C-terminal histidine kinase domain; the master circadian transcriptional regulator RpaA; CikA, which plays roles in both the input and output mechanisms. Additionally, KaiB morphs from an inactive tetramer in a ground-state fold to an active fold-switched monomer, capable of interacting with KaiC. (B) Over the course of the day SasA becomes activated as a kinase towards RpaA via an association with KaiC, with RpaA-P peaking at dusk. Red dots represent phosphorylation events. Once KaiC has reached the fully phosphorylated state rare fs-KaiB monomers are stabilized by binding to KaiC at a site that partially overlaps with SasA binding, likely dislodging SasA from KaiC. Additionally, fs-KaiB engages CikA, activating its phosphatase activity towards RpaA, causing RpaA-P levels to decrease at night. Graphics courtesy of the UC San Diego Bio Clock Studio.

expression. Surprisingly, RpaA-P binds directly to only ~100 positions in the genome; however, essentially the entire *S. elongatus* genome is expressed rhythmically. Included amongst the ~170 genes expressed as part of the RpaA regulon are those that encode 4 sigma factors, suggesting that RpaA-regulated global rhythms of gene expression are carried out via the activation of a transcriptional cascade. Additionally, RpaA-P directly regulates genes required for metabolism (glycolysis, glycogen and oxidative pentose phosphate pathways), proteolysis, and the bacterial tubulin homolog FtsZ, suggesting that processes such as energy production/storage, protein homeostasis and cell division are closely tied to the clock. However, this picture is not complete, as we know that RpaB, a paralog of RpaA that is regulated not by clock but by the environment, also plays a role in controlling diurnal gene expression. While roles for RpaB in rhythmic gene expression have yet to be determined, RpaB can inhibit the phosphorylation of RpaA, and binding of RpaB to some promoters is antagonized by RpaA, suggesting that RpaB is a hub that integrates both circadian and environmental information to regulate gene expression rhythms.

One of the primary reasons that circadian rhythms were originally not expected to be a property of bacteria is that many bacteria have a doubling time shorter than a day. Intuitively, an organism whose life cycle was less than 24-h did not seem to need a circadian clock. Work in *S. elongatus* demonstrated that the rhythmicity of the clock is independent of the cell division cycle. The clock maintains ~24-h periodicity whether the cells are dividing multiple times or not at all in a 24-h time period. Moreover, single-cell analysis has shown that the phase of the oscillator is robust at the single-cell level and is inherited from mother to daughter cell with negligible intercellular coupling. In populations of rapidly dividing cells a TTFL involving RpaA-activated transcription of *kaiABC* helps to maintain robustness of the clock, because enhanced variations in phase are observed in single cells when the TTFL is compromised. These results suggest that, while a TTFL is not the primary driver for rhythms of gene expression, such a loop is important for the sustained robustness of the post-translational oscillator under certain circumstances, perhaps via buffering protein levels in individual cells. Although cell division is not synchronous in *S. elongatus*, there is an ~6-h block of time in the early subjective night (i.e., circadian night, even in the absence of an environmental cycle) when cell division is specifically inhibited by the circadian clock. The mechanism by which this inhibition or gating occurs is unknown; however, the current model proposes that the clock regulates the expression of a factor or set of factors that inhibit the bacterial tubulin homolog FtsZ from forming the cytokinetic ring at mid-cell.

One virtue of the *S. elongatus* circadian clock, in comparison to those of eukaryotes, is that the core oscillator can be reconstituted *in vitro*. Moreover, the *in vitro* system mimics the *in vivo* system so well that it has led to many key insights into clock function. Nonetheless, there are aspects of the *in vivo* system that cannot be reproduced *in vitro*. An example is the natural variation in protein abundance: KaiB and KaiC exhibit robust oscillations in cellular protein levels throughout the day, whereas KaiA levels remain nearly constant. Another is that KaiA and KaiC change their subcellular localization patterns over the course of the day. Specifically, KaiA and KaiC are diffuse throughout the cell during the daytime portion of the cycle, but then become localized to a cell pole at night. The nighttime complex at the poles of cells also includes CikA, which is consistent with the known roles for CikA in the circadian mechanism. The observed changes in protein levels and subcellular localization patterns likely relay information to and from the input/output pathways and influence the robustness of the clock in the context of a cell, which is a much more complex system than a test tube.

Mutants with an altered clock or absent clock grow about as well as WT strains in constant light, which raises the question of whether the circadian clock is of any use to the cell. Key experiments performed by Johnson and colleagues showed that, while clock mutant strains do not exhibit a growth defect when grown in pure culture, a competitive fitness advantage is conferred to strains whose internal period matches the external environment. For example, when a WT strain with a FRP of ~25-h is co-cultured with a short-period mutant that has an ~22-h FRP, the WT strain will outcompete the short-period mutant if the mixed culture is grown in a 12-h light:12-h dark cycle (LD 12:12). However, in a shorter day cycle of LD 11:11, the short-period mutant will outcompete the WT. These experiments were the first to demonstrate experimentally, for any organism, the long-accepted assumption that circadian clocks confer a fitness advantage.

A Circadian Clock With Atomic Resolution

Recent structural investigations provided critical insights into clock function including the nature of KaiB's roles in timekeeping and time delay as well as relaying temporal information to clock-controlled activities. The structures of KaiA, KaiB and KaiC were solved more than a decade ago by X-ray crystallography and/or NMR spectroscopy. Structural analysis of each component has shown that KaiA is a homodimer, with each monomer comprising two independently folded domains: an N-terminal PsR domain, which binds oxidized quinone, and a C-terminal KaiC-interacting domain, connected by a linker. KaiC is a hexameric protein in which each monomer bears two homologous domains, CI and CII, such that oligomerization creates stacked hexameric rings. Although the CI and CII domains are duplications, the phosphorylation sites Ser 431 and Thr 432 are limited to the CII domain. However, the CI domain of KaiC possesses a weak ATPase activity, which hydrolyzes only ~15 molecules of ATP per day per KaiC monomer. The ATPase activity is temperature compensated and is important for the periodicity of the circadian clock. The structure of KaiB in isolation has been solved by several labs and was demonstrated to be a tetramer that took on what was referred to as a rare fold.

While the structure of each Kai protein had been solved individually, visualization of the KaiABC complex long remained elusive. Moreover, the mechanism by which KaiB inhibits KaiA stimulation of KaiC autophosphorylation had long been a mystery. The site of KaiB's association with KaiC was also contentious, as some groups presented evidence that it associated with the CII domain of KaiC while others proposed that it associated with the CI domain. The structure of KaiB in association with KaiC as well

as the KaiABC complex structure were conclusively resolved in 2017 (see Chang *et al.* and Tseng *et al.*), solving some long-standing mysteries and also leading to a few surprising discoveries. First, KaiB was shown to interact with the B-loops present in the CI domain. Although, CI and CII are homologous, the B-loops are present only on the CI domain of KaiC, where they remain hidden until KaiC becomes phosphorylated on S431. Only after S431 becomes phosphorylated are the B-loops get exposed, allowing KaiB to bind to the CI domain of KaiC. However, the real surprise came in the discovery that KaiB bound to KaiC not as a tetramer but rather as a monomer, capable of forming an additional hexameric ring on KaiC. Moreover, this monomeric form of KaiB had a completely different structure than the rare fold adopted in the tetrameric form. KaiB that associates with KaiC adopts a thioredoxin-like fold, which happens to be the same fold as the N-terminus of SasA. We now know that the KaiB is part of a class of metamorphic proteins capable of reversibly changing its structure. The rare fold in the tetrameric structure represents an inactive form of KaiB that is not capable of associating with KaiC, also referred to as ground-state KaiB (gs-KaiB). KaiB must morph, via unfolding and refolding, into an active, fold-switched (fs-KaiB) state in order to be competent to associate with KaiC (Fig. 2(A)). This switch from gs- to fs-KaiB is rare and unstable; the fs-KaiB fold is stabilized only in association with exposed B-loops on KaiC. The instability of KaiB's fold-switched form explains why it had not been discovered until its atomic structure was resolved in its KaiC-bound state. Moreover, the expectation that the structure that had been crystallized would associate with KaiC confused the analyses that pointed to binding on the CII domain. The switching from inactive gs-KaiB to active fs-KaiB, and the requirement for a specific status of KaiC to bind and stabilize it, accounts for a significant portion of the 24-h period of KaiC phosphorylation reaction cycle. Because thioredoxin is an ancient fold, perhaps fs-KaiB is the ancestral form of KaiB and evolution of the inactive, gs-KaiB, was an important evolutionary step in acquiring a clock mechanism.

This new understanding of how KaiB associates with KaiC also shed light on how KaiB inhibits KaiA and promotes the autophosphatase activity of KaiC, switching the oscillator from a daytime to a nighttime mode. Once in the fully phosphorylated state, the CII ring of KaiC stacks tightly onto the CI ring, causing the B-loops to become exposed. When fs-KaiB is present it can rapidly associate with the newly exposed B-loops, ultimately forming a ring consisting of 6 fs-KaiB monomers on the CI domain of KaiC. In addition to associating with KaiC, fs-KaiB can bind and sequester KaiA away from the A-loops of KaiC, promoting KaiC autophosphatase activity during the nighttime portion of the cycle. Recent structural work has shown that fs-KaiB associates with an auto-inhibited form of KaiA, which has undergone a large-scale conformational change such that its KaiC interaction domain is unavailable. Thus, KaiA can no longer stimulate KaiC kinase activity in CII because it has been sequestered by KaiB on CI, and cannot stimulate the activity of a neighboring KaiC from its KaiB-bound position because it is in an auto-inhibited conformation (Fig. 2(B)).

The identification of fs-KaiB also led to critical insight as to how the oscillator communicates information to the output pathway. SasA that is not in association with KaiC is not competent to phosphorylate RpaA. When the N-terminal domain of SasA associates with the CI domain of KaiC, at a site that partially overlaps with the B-loop, SasA becomes activated as a kinase towards RpaA. The binding of fs-KaiB to the B-loops, occurring after S431 phosphorylation of S431, likely displaces SasA from KaiC. Additionally, fs-KaiB in the KaiBC complex interacts with CikA, stimulating its phosphatase activity. Thus the binding of fs-KaiB to KaiC not only switches KaiC from a daytime autokinase mode to a nighttime autophosphatase mode, but also inactivates SasA as a kinase toward RpaA and activates CikA as a phosphatase towards RpaA, resulting the rhythms of RpaA-P and, thus links the oscillator to output function.

Variations on the KaiA-KaiB-KaiC Oscillator

The *S. elongatus* KaiABC oscillator is the only prokaryotic circadian clock whose molecular details have been elucidated. In *S. elongatus* KaiA, KaiB, and KaiC are all essential components of the clock. However, variations of the KaiABC system exist amongst cyanobacteria. Here, we discuss cyanobacteria that encode homologs of *kaiB* and *kaiC* but not *kaiA*, as well as species that encode multiple paralogs of *kaiB* and *kaiC*.

While circadian rhythmicity that persists in the absence of external cues is a property of many cyanobacterial species, it may not be present in all cyanobacteria. *Prochlorococcus marinus*, one of the predominant primary producers in the open ocean, likely has an hourglass timer that is not self-sustained in the absence of external cues. In the laboratory as well in natural populations, *P. marinus* growing in an LD cycle display a daily cell cycle rhythm, where the DNA is replicated in the afternoon and cell division occurs in late afternoon/early evening, as well as rhythms of gene expression. However, these rhythms quickly damp in constant light. These data suggest that the *P. marinus* clock functions as an hourglass timer, requiring the rising of the sun to initiate a 24-h program of temporal regulation. While the *P. marinus* genome has *kaiB* and *kaiC* homologs, it appears to have lost the full length *kaiA* sequence, with a remnant *kaiA* gene remaining. In contrast to the *S. elongatus* KaiC, whose autophosphatase activity dominates when the protein is in isolation, KaiC from *Prochlorococcus* sp. MED 4 exhibits ATPase activity and readily autophosphorylates on serine 427 and threonine 428. *Prochlorococcus* also lacks *cikA* homologs, consistent with the notion that *cikA* is evolutionarily the newest member of the circadian network. Moreover, an hourglass timer that responds directly to the environment may not require a protein such as CikA that functions to entrain the core oscillator, consistent with its absence in *Prochlorococcus*. The molecular details of how the *Prochlorococcus* clock functions are still unresolved and the lack of molecular genetics in this system has hindered progress in this area.

The loss of *kaiA* is not the only variation to the *kaiABC* theme among diverse cyanobacteria. Several cyanobacterial species including the model system *Synechocystis* sp. PCC 6803 have one *kaiA* gene and three paralogs of *kaiB* and *kaiC*. Using luciferase

reporters the *kaiA-kaiB1-kaiC1* locus of *Synechocystis* has been shown to be required for cyclic gene expression. As in *S. elongatus*, KaiC1 autophosphorylation is dependent on KaiA. However, KaiC2 and KaiC3 can autophosphorylate independently of KaiA. While it still remains to be determined how each of the three *kai* clusters may contribute to the circadian clock and rhythmic phenomena, it has been proposed that *kaiB3* and *kaiC3* are important for fine-tuning the period length and phase of the clock whereas *kaiB2* and *kaiC2* have no attributable clock functions. However, supporting data for these proposed functions of *kaiB2*, *kaiC2*, *kaiB3* and *kaiC3* have not been published.

Our understanding of how circadian clocks function is dependent on our ability to grow and manipulate the organisms in a laboratory setting. Their function in the organisms' native environments have not been studied as extensively. Time-resolved whole-genome transcriptome profiling of marine microbial populations over a 3-day period found robust 24-h diel oscillations of cyanobacterial transcripts; surprisingly, it also revealed diel cycling of transcripts in heterotrophic bacterioplankton that follow those of the photosynthetic organisms. One hypothesis is that the heterotrophic bacterioplankton are responding to metabolic cues from the cyanobacteria, thus resulting in staggered multispecies waves of diel gene expression in the ocean. The metabolic coupling between primary producers (cyanobacteria) and consumers (heterotrophic bacteria) results in the coordination of diverse biogeochemical activities in complex microbial communities, such as in the ocean.

Kai Genes Outside of Cyanobacteria

While the *kai* genes have been studied extensively only in cyanobacteria, potential homologs of *kaiB* and *kaiC* (but not *kaiA*) are found in eubacteria and Archaea. While evidence for 24-h timing systems is clear in many of these organisms, some appear to possess an hourglass timer whereas others may have a free-running circadian clock. Although the existence of circadian timekeeping in some of the organisms discussed below may seem obvious, the definitive experiments to demonstrate the existence of a robust mechanism that satisfies the three criteria accepted to comprise a *bona fide* circadian clock have not yet been performed, nor has the role for the *kai* homologs in these organisms been explored.

Phototrophic bacteria including purple bacteria and the green nonsulfur bacterium *Chloroflexus* have homologs of *kaiB* and *kaiC*, but not of *kaiA*. Extrapolating from what is known in *Prochlorococcus*, a KaiBC-based hourglass timer may be present in these organisms. However, the purple bacterium *Rhodospirillum rubrum*, which grows photosynthetically under anaerobic conditions, exhibits sustained rhythms of gene expression, as monitored using a luciferase reporter system, suggesting the existence of a circadian oscillator. Under aerobic conditions, where the organism grows chemoheterotrophically, these rhythms exhibit a 20.5-h period and under anaerobic, photosynthetic conditions they have an ultradian period of 10.6–12.7 h. A related purple non-sulfur bacterium, *Rhodospseudomonas palustris*, which similarly exhibits different growth modes depending on the availability of oxygen, displays rhythms of nitrogen fixation in LD. However, these rhythms do not persist in constant light. A mutant that lacks *kaiC* also exhibits nitrogen fixation rhythms in LD, but with a peak time that varies from WT, suggesting a role for *kaiC* in the phasing of these rhythms. *R. palustris* KaiC is capable of autophosphorylation, but rhythms of KaiC phosphorylation were not observed in LL *in vivo*. Taken together, these data suggest that KaiB and KaiC proteins play roles in both circadian and hourglass timekeeping mechanisms. Additionally, these data may suggest roles for the cyanobacterial-specific KaiA in promoting sustained rhythmicity in the absence of external cues.

Potential *kaiB* and *kaiC* homologs have been found in eubacteria as well, but their functions have not been investigated. In the human pathogen *Legionella pneumophila* *kaiB* and *kaiC* are expressed in an operon under the control of the stress sigma factor RpoS, and have been proposed to function in stress-resistance pathways, but tests for circadian rhythmicity have not been performed. Intriguingly, the crystal structure of KaiB in isolation from *L. pneumophila* has been solved and was found to adopt the fold-switch or thioredoxin-like fold. These data support the notion that the thioredoxin-like fold is ancestral, and that the ground state in *S. elongatus* is an adaptation that enabled the evolution of the clock.

There is also evidence for circadian rhythmicity in archaea. In the halophilic archaeon *Halobacterium salinarum* NRC-1 12% of all genes show ~24-h rhythmicity in LL after 3-day entrainment to an LD cycle. While mechanistic studies in this organism have not been performed, a related haloarcheon, *Haloferax volcanii*, has four cryptic *kaiC*-like genes, *cirA*, *cirB*, *cirC*, and *cirD*, that have been the subject of some investigation. While *kaiC*-like genes were identified, no homologs of *kaiA* or *kaiB* were found in this organism. *CirA*, *CirB* and *CirD* are single-domain proteins that share 48%–55% similarity to the CI domain of KaiC from *S. elongatus* and do not have a CII domain. The clock in *S. elongatus* requires both domains in order to function as the circadian timekeeper, as interdomain interactions figure largely in the timing mechanism. *CirC*, on the other hand, has a double-domain structure similar to KaiC of *S. elongatus*. Expression of the *cir* genes oscillates with daily periodicity in LD but not in LL. Intriguingly, rhythms of gene expression in LD are lost if any of the *cir* genes is disrupted, implicating all as participating in diel cycling. However, limitations of working with these archaeal species have hindered progress in this area.

Some reports have identified peroxiredoxins as a conserved marker of circadian rhythms across all domains of life. Peroxiredoxins are a ubiquitous type of antioxidant enzyme. Peroxidase activity is dependent on the oxidation state of a key cysteine residue; once this residue is hyperoxidized it is catalytically inactive and can be recycled. Peroxiredoxins that undergo ~24-h redox cycles that persist for several days in the absence of external cues, and are entrainable and temperature compensated, have been reported in species across all three domains of life including circadian systems *S. elongatus*, flies, fungi, plants and also in archaea and even red blood cells. While eukaryotic circadian oscillators are driven by TTFLs, red blood cells lack a nucleus and could not support such a mechanism, suggesting that peroxiredoxin redox rhythms are driven by a posttranslational mechanism. In *S. elongatus* peroxiredoxin redox rhythms persist even when the *kai*-based oscillator is compromised, albeit with altered phasing. This finding

suggests that the KaiABC complex do not drive peroxiredoxin redox rhythms, but the two oscillators are somehow coupled. Similarly, the peroxiredoxin-redox oscillator is not dependent on known clock components in eukaryotic systems, suggesting the existence of a novel timing mechanism that predates more recently evolved robust circadian oscillators. These results, with the observations from *Legionella* and archaea, suggest that Kai proteins may have functions beyond acting as a circadian oscillator and that Kai proteins may not be the only drivers of prokaryotic circadian clocks.

Microbiome Rhythms

Recently, there has been an explosion of work demonstrating the importance of the human gut microbiome (the ~100 trillion microbes that reside in our gut, also referred to as microbiota) to human health and disease. The composition and function of the microbiome exhibits 24-h diurnal oscillations that are important for metabolic homeostasis of the host. Functional profiles of the microbiome at different times of day reveal that energy harvest, DNA repair, and cell growth primarily occur during the active phase of the host, whereas detoxification and chemotaxis are more prevalent during the host resting period. These microbiome rhythms are not self-sustained and are dependent on the circadian clock of the host. Oscillations in neither abundance nor function of the microbiome are observed if the host circadian clock is perturbed. Intriguingly, changes in microbiota induced by jet-lag led to enhanced weight gain and glucose intolerance compared to control microbiota samples, highlighting the importance of microbiota rhythmicity to human health.

In addition to light perceived through the eyes, we now know that food intake is an important input to the mammalian circadian clock. Mice fed a high-fat diet exhibit attenuated clock function, and these adverse effects can be prevented with time-restricted feeding, suggesting that the cause of attenuation is not the high-caloric diet itself but rather the misalignment of nutrient availability with circadian metabolic activity. Not surprisingly, microbiota oscillations are controlled by feeding time of the host in addition to regulation by the host circadian clock.

While the host circadian clock regulates rhythms within the microbiome population, new evidence suggests that the reverse is also true. Oscillations in key microbial-derived metabolites can regulate or modify the host central and hepatic circadian rhythm and host metabolic function. Alteration to microbiota rhythms resulting in inappropriate timing of key metabolites can alter circadian rhythms of gene expression in the liver and promote diet-induced obesity. Additionally, the location of particular members of the microbiome changes over the course of the day. Oscillating biogeographical distribution of the microbiome, as well as oscillations in metabolism, determine rhythmic exposure of the intestinal epithelium to different bacterial species and their metabolites over the course of the day. Thus, the host circadian clock regulates rhythmicity in population, function, and location of the gut microbiome. In turn, metabolites produced by the microbiome provide critical feedback to the host circadian clock.

Because the observed oscillations in the gut microbiome are not self-sustained, but rather dependent on the host clock, it would suggest that these rhythms rely on an hourglass timer. However, it is possible that some members of the microbiome community possess a circadian clock themselves. In fact, one member of the microbiome community, *Enterobacter aerogenes*, exhibits circadian patterns of swarming and motility as well as gene expression in response to the neurohormone melatonin. These rhythms can be entrained to the presence of melatonin and are temperature compensated. However, *E. aerogenes* does not encode homologs of *kaiA*, *kaiB* or *kaiC*, suggesting that a novel mechanism is driving these rhythms. One possibility is that this oscillator is the same as the one that drives peroxiredoxin oscillations. The motility, and therefore localization, of bacterial species within the gut may be controlled by the microbial circadian clock. Further investigation is sure to lead to new insights into the interplay between the microbiome and the host.

The discovery of circadian clocks in cyanobacteria surprised a community that underestimated the sophistication of prokaryotic cells and organisms. Work in *S. elongatus* has led to an exquisite understanding of how bacterial circadian clocks function. However, circadian rhythms in prokaryotes are likely not limited to cyanobacteria, as examples of bacterial rhythms are now being discovered everywhere. Moreover, work from organisms outside of *S. elongatus* has led to the idea that Kai proteins may have functions outside of the circadian clock system and that there are prokaryotic clocks that are not composed of Kai proteins (Table 1). While circadian

Table 1 Summary table of different species, the genes that have been tied to clock behaviors, and whether the observed rhythmic behaviors are circadian, hourglass or unknown. Circadian? represents organisms for which the existing data are highly suggestive of a circadian clock; however, the definitive experiments have not yet been performed

Organism	Clock genes	Clock
<i>S. elongatus</i> PCC 7942	<i>kaiA</i> , <i>kaiB</i> , <i>kaiC</i>	Circadian

<i>Halobacterium salinarum</i> NRC-1	<i>cir</i> genes	Circadian?
<i>Enterobacter aerogenes</i>	Not known	Circadian?

biological oscillators can be found ubiquitously throughout nature, hourglass timers, which require cues from the environment to be sustained, are also important for coordinating activity over the course of the day. Studies of environmental systems and bacterial-host interactions have led to the notion that circadian oscillators can work in conjunction with hourglass timers to orchestrate the timing of a complex community. Continued research in this area is required to determine their mechanisms, but the next few years are sure to be an exciting time for bacterial circadian rhythms.

Glossary

Acetone–butanol fermentation A bacterial fermentation carried out by certain sugar-metabolizing species of *Clostridium*. The typical end products include acetone, *n*-butanol, and acetic acid (collectively referred to as ‘solvents’).

Anaerobe An organism that has the ability to grow in the absence of oxygen.

Antitoxin Protective factors, usually antibodies, produced in animal and human sera in response to injection with toxin or detoxified toxin (toxoid).

Bioremediation Conversion of pollutants to nontoxic compounds by microorganisms and enzymes.

Botulinum neurotoxin The most poisonous toxin known for humans and certain animals and the cause of botulism. Botulinum neurotoxin is also being increasingly used for the treatment of a diversity of disease syndromes and for cosmetic enhancement.

Botulism The rare paralytic disease of humans and other animals caused by the potent neurotoxin produced by the bacterium *Clostridium botulinum*.

Clostridium Obligately anaerobic, endospore-forming bacteria that occur widely in soils and in the intestines of animals and occasionally humans.

Endospores Resistant bodies formed by certain genera of bacteria, including *Bacillus* and *Clostridium*.

Enzymes Biochemical compounds (particularly enzymes) that catalyze chemical reactions.

Fermentation Energy-yielding metabolism in which an energy substrate is metabolized without the molecular involvement of an external electron acceptor, such as oxygen.

Gas gangrene A rapidly spreading disease that results from the infection of a wound by certain anaerobic bacteria, particularly by species in the genus *Clostridium*.

Tetanus The extremely painful and often deadly spastic disease (commonly called lockjaw), affecting humans and animals, produced by the bacterium *Clostridium tetani*.

Toxins Microbial products or components that cause injury or disease in multicellular organisms, including humans and animals. The clostridia produce more protein toxins than any other bacterial group.

Vaccine An antigenic preparation administered to humans that elicits protective immunity to a specific pathogen or toxin.

Defining Statement

Clostridium comprises a genus of spore-forming, strictly anaerobic bacteria that have important roles in human disease and in biotechnology. This article describes their biological properties and their importance to humankind.

Introduction

The clostridia are an extremely diverse group of bacteria, and several species have an illustrious history in medical microbiology and in biotechnology. Clostridia were probably first alluded to in history by the Greek physician Hippocrates from the island of Kos (460–370 BC), who reported on wound infections in his *Epidemics III*. The symptoms were a yellowish-red swelling in the wound and followed by the formation of copious pus. In severe cases, flesh was destroyed and limbs were lost. Tetanus, commonly referred to as lockjaw, was vividly illustrated in Sir Charles Bell’s *Essays on the Anatomy and Philosophy of Expression* (1824), in which in a painting he depicted a soldier in agony from severe contractions. The famous original painting can be observed in the museum at the Royal College of Surgeons of Edinburgh. In World War I, wound infections caused by clostridia were common among soldiers and caused much suffering and mortality. Clostridia also have several positive characteristics and utilities in industry and medicine. They have been used as a source of fine chemicals, solvents, and enzymes used in the chemical industries, and clostridia are ecologically important in the degradation of various xenobiotics. One of the most remarkable attributes of clostridia is the development of botulinum neurotoxin for the treatment of a variety of neurological maladies by direct injection of small quantities of toxin into neuromuscular tissue. Botulinum toxin is also used in cosmesis, for the presumptuous beautification of the human body.

This article is an update of E.A. Johnson, Clostridia, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 87–93.

Clostridia grow only in the absence of oxygen and are characterized as obligate anaerobes. Although life without oxygen was envisioned as early as 1680 by Antonie van Leeuwenhoek, the discovery of life without oxygen was by Pasteur, who showed in the mid-1800s that butyric acid formation by clostridia occurred in the absence of oxygen. Pasteur devised anaerobic culture conditions by boiling the medium to drive out absorbed gases from the culture medium and by using anaerobic culture conditions. He isolated an organism that grew and produced butyric acid under anaerobic conditions; he called this organism '*Vibrio butyrique*,' which probably corresponds to *C. butyricum*, the type species of the genus *Clostridium*. In 1877, Pasteur and Joubert also described the first pathogenic anaerobe of humans and animals, now known as *C. septicum*, which is a serious cause of wound infections and bacteremia or blood infections. *C. tetani*, the cause of lockjaw or tetanus in humans and animals, particularly horses, was discovered in 1889 by Nicolaier, who enriched the spores from pus from a lesion of an animal that had died. Kitasato isolated the organism in pure culture and showed that it produced a potent toxin, which when injected in an inactive form into animals gave rise to specific antitoxin in the serum that was protective against the disease when administered prophylactically. This groundbreaking research contributed to the development of vaccines, currently used for the prevention of disease in billions of humans and animals.

Interest in clostridia was also stimulated by their roles in food spoilage and foodborne disease. Several species of clostridia grow at refrigerator or high temperatures and spoil foods, which is noted by gas production from carbohydrate fermentation, putrid smells from protein degradation, and detriments in texture and organoleptic properties of the foods. Several clostridia are highly resistant to heat and survive canning and cooking processes by virtue of their ability to form spores and subsequent germination of the spores and growth leading to spoiled cans and packages that may explode due to gas formation. Several federal laws implemented for food preservation and food safety have been derived to prevent the survival and growth of *C. botulinum*, which has highly resistant endospores and produces its extremely potent neurotoxin that is the cause of the disease botulism.

Clostridia have had important historical and contemporary roles in various biotechnological processes. Reports indicate that clostridia were used by the Romans for the production of indigo for dyeing of the skin and later for linen, paper, and other materials. Pasteur found in the 1860s that clostridia produced different solvents and acids including butanol and butyric acid. Certain nonpathogenic clostridial species are important in the formation of solvents and organic acids by anaerobic fermentations and as sources of enzymes for biocatalysis. The importance of clostridia in industrial fermentations was demonstrated prior to World War I, when an industrial process was developed for butanol as a precursor of butadiene (for synthetic rubber) and of acetone, used in the manufacture of munitions. Solventogenic clostridia are currently being extensively studied for the production of acetone and butanol by fermentation from renewable agricultural materials. Another important biotechnological process of clostridia was their use in flax retting, resulting in the production of clothing and oil. In the twentieth century to the present, clostridia have been investigated as sources of novel enzymes for biotransformations, for biomass degradation, and for their ability to degrade pollutants and xenobiotics.

A remarkable discovery postulated in the eighteenth century that became a reality in 1970–80s and escalating in importance to the present is the use of botulinum neurotoxins as pharmacological agents for the treatment of a diversity of neurological diseases including movement disorders, pain syndromes, cerebral palsy, spasticity, depression, excessive sweating, and more than 100 syndromes. The basis for therapeutic use of botulinum neurotoxin is its absolute specificity and action on nerves in the peripheral system. It blocks the release of the neurotransmitter acetylcholine, thus quieting the activity of muscles adjacent to the affected nerves. The toxin has also been used for cosmetic purposes such as smoothing frown lines, crow's feet, and other appearances that come with age. Recent evidence indicates that botulinum toxin can enter the central nervous system and lead to relief of mood and affect disorders.

Owing to the extreme toxicity of botulinum neurotoxin, it has been considered as potential agents of bioterrorism. Historically, botulinum toxin was administered to prisoners in certain cultures and regimes. In 1990, during the first Gulf War, it was acknowledged that 20 000 l of botulinum toxin was produced and potentially weaponized on missiles. The Japanese cult sect Aum Shinrikyo attempted to dispense aerosolized botulinum neurotoxin in metropolitan Tokyo. Fortunately, the cult was unsuccessful in producing active aerosols of the toxin. These attempted incidences and evil plans have raised awareness regarding the potential use of botulinum neurotoxin as a bioterrorist agent.

The importance of clostridia in medical and industrial microbiology contributed significantly to the development of important microbiological techniques. The culturing of strict anaerobes from the environment and infected humans and animals, as well as the strictly anaerobic colon of mammals, presented a considerable challenge to scientists. It became necessary to develop oxygen-free culture media and equipment including anaerobic incubation systems to isolate and study the clostridia and other strictly anaerobic microorganisms. The availability of anaerobic culture techniques led to the discovery of many new groups of organisms and recognition of unique pathways of anaerobic metabolism.

Properties of Clostridia

Classification

The genus *Clostridium* was first proposed in the mid-1800s. Since then, most anaerobic endospore-forming bacteria have been included in the genus. The genus *Clostridium* belongs to the family Bacillaceae of the phylum Firmicutes of Bacteria. The genus *Clostridium* comprises a large and diverse group of at least 12 lineages of anaerobic and occasionally aerotolerant, Gram-positive, rod-shaped bacteria that form resistant endospores. The endospores are often wider than the vegetative organisms in which they arise, giving cells the characteristic spindle shapes or clostridium forms. The clostridia have certain common properties: (1) a Gram-positive cell wall structure, (2) formation of resistant endospores that often swell the cell, (3) an anaerobic and fermentative metabolism, and (4) the inability to reduce sulfate to sulfide. The genus *Clostridium* has a wide range of 21–54 mol% GC content of their DNA, supporting the heterogeneity of this group of organisms.

Traditionally, clostridia are classified on the basis of morphology, spore formation, and physiological properties including anaerobiosis and fermentative metabolism, disease association, toxin formation, DNA relatedness, and ribosomal RNA gene sequence homologies. The vast majority of clostridia have a rod-shaped morphology and are motile by peritrichous flagella. Several taxonomic groups of *Clostridium* have been described on the basis of nucleic acid homologies; sequencing of macromolecules, particularly 16S rRNA; mol% GC; cell wall structure; production of toxic and antigenic proteins; and type of anaerobic metabolism. Advances in whole genome sequencing are becoming more important in the classification of clostridia. Currently, more than 200 species have been proposed, and *Clostridium* represents one of the largest genera of prokaryotes. The genus needs to be better defined by traditional and advanced molecular methods to delineate natural lineages.

Habitat

The clostridia are widely distributed in nature by virtue of their ability to form environmentally resistant endospores and by their diverse metabolic properties. The clostridia appear to reside in two primary habitats: soils and water sediments throughout the world and within the gastrointestinal tracts of certain animals. Some species inhabit the human gastrointestinal tract, and ~40 species have been found in human feces, including several pathogenic species. Many species of pathogenic clostridia are free-living and generally do not have an obligate association with an animal host, in contrast to many other pathogenic bacteria. One species, *C. perfringens*, has been found in nearly every soil sample worldwide for which it has been sought. Since spores of clostridia are present in the soil, they are associated with many foods, including vegetables and milk, as well as in environmental sources such as dust and sewage. Although most species usually lead a strictly saprophytic nonpathogenic existence, several species are the cause of well-recognized diseases in humans and animals mainly through the production of potent toxins.

Physical Properties

The clostridia vary widely in their structure and in certain physical properties. Most clostridia are rod-shaped; however, some species are pleomorphic, and morphology of a strain differs markedly, both among and within species. The morphology of the strains and the presence of endospores vary depending on the stage of the growth cycle. Generally, clostridia are large, rod-shaped organisms that range approximately from 0.4 to 1.3 μm in breadth and from 3 to 8 μm in length. The vegetative forms often occur singly, in pairs, or as long chains. Most of the clostridia are actively motile by peritrichous flagella.

Clostridia produce specialized structures, referred as endospores, which are very resistant to heat, radiation, drying, and chemicals. All *Clostridium* species are able to form spores, but there is considerable variation in the formation in nature and in the laboratory. Spores can be visualized by phase-contrast microscopy. The spores of most species are wider than the vegetative cells, imparting a distinctive appearance depending on where they are formed within the cell. When they are formed at the equator, the cells are spindle-shaped; when present or terminally, they impart a marked club-shaped or tennis racket appearance (Figure 1). Spores of most species can be produced in chopped meat broth or in complex media such as trypticase–peptone–glucose–yeast extract, a clear medium from which they can be purified and studied.

The spores released from the mother cell are distinct in structure and resistance properties. They are low in water content, possess distinct layers and compartments, and resist inactivation by heat, other physical treatments, and exposure to chemical agents. They are dormant and exist in an inactive solid state. Certain clostridia, such as *C. botulinum*, produce spores of high heat resistance, and the spores will remain viable after boiling in aqueous media for more than 1 h. This is the reason that additional barriers are needed to prevent clostridial growth when minimal heat treatment is used in many foods. Inactivation of *C. botulinum* spores or control of spore germination and outgrowth provides the basis for many food processing technologies and food regulation laws. Survival of spores of nonpathogenic heat-resistant mesophilic and thermophilic spores during processing of foods can lead to huge economic losses.

Figure 1 Characteristic morphology of *Clostridium botulinum* with the presence of endospores. The photograph shows a phase-contrast visual micrograph ($\times 750$) of a culture of *C. botulinum* type A.

Metabolic Properties

The clostridia are sensitive to oxygen and only grow under anaerobic conditions. They fail to thrive in aerobic environments, which differentiate them from aerobic spore formers including the anthrax bacillus (*Bacillus anthracis*) and the common hay bacillus (*B. subtilis*), which has been used extensively as a model organism for the study of sporulation and other properties. Under permissive environmental and nutritional conditions, spores germinate to form vegetative cells that divide by binary fission to reach high cell numbers in suitable nutritional media. When nutrients are limiting, vegetative cells form endospores in an intricate differentiation process. The spores exist as dormant bodies until they encounter a permissive growth environment, and the spores germinate, thus perpetuating the vegetative/spore cycle. In certain clostridia such as *C. perfringens*, extracellular toxin formation appears to coincide with sporulation, while in other species such as *C. botulinum* and *C. tetani*, the highest yields of toxin occur in populations of vegetative cells that do not sporulate.

Species differ widely in the substrates that they ferment. Some species ferment biomass including cellulose, starch, hemicellulose, and pectins by virtue of production of extracellular degradative enzymes, and they anaerobically convert the resulting sugars to ethanol, organic acids, and other products including various gases. Several species are putrefactive, degrading proteins with the formation of odorous nitrogenous products characteristic of rotting foods. Some clostridia can utilize nucleic acids, purines, and pyrimidines, and a few species such as *C. pasteurianum* utilize molecular gaseous nitrogen as their sole source of nitrogen and convert it to organic nitrogen cellular components (nitrogen fixation).

Some species of clostridia can grow over a wide range of pH and temperatures. Most species prefer growth within the pH range of 6–7, but some grow at pH below 4 or above 8. Clostridia favor temperatures of growth from 25 to 37 °C, but several species of psychrophilic clostridia grow at temperatures below 10 °C and several thermophilic species grow at temperature above 60 °C. The psychrophiles are important in food spoilage, while many of the thermophilic clostridia are valuable as sources of durable enzymes for industrial processes.

Special considerations are needed for isolation and cultivation of clostridia. First, since most species are strict anaerobes, specialized equipment and methodologies are required to provide an anaerobic environment for growth. Anaerobic jars, specialized culture tubes, glove boxes, and reduced media are needed to exclude oxygen and provide the needed redox environment. Second, clostridia tend to grow as mixed cultures with other anaerobes, and strict attention is needed to affirm the purity of the culture under study or the culture used in an industrial process. Many clostridia are subject to bacteriophage infection that will decrease solvent, enzyme, or toxin yields. Safe laboratory practices and immunization of personnel may be needed for the study of toxigenic species such as *C. botulinum* and *C. tetani*.

Genetics of Clostridium

The genetic study of the clostridia is in its infancy, but significant advances have been made in recent years. The application of molecular biology techniques and genomics has led to certain genetic tools including cloning and expression vectors and gene inactivation systems. Gene transfer technology using transformation (usually electroporation) or conjugation has been developed for *C. perfringens*, *C. acetobutylicum*, *C. difficile*, and *C. botulinum*, and genetic tools to understand virulence and to improve industrial processes are becoming increasingly available. The achievement of the complete genome sequences of a growing number of *Clostridium* spp. has provided a foundation for elucidating important genetic and phenotypic properties and for providing interesting comparative lifestyle and evolutionary analyses. Since the coding genomic DNA of most clostridial species is A–T-rich, it can be difficult to express cloned clostridial genes, such as in *Escherichia coli* or *Saccharomyces cerevisiae*, due to the limited availability of the required cognate tRNAs for protein synthesis. Much work is still needed to elucidate the modes of genetic regulation and the integration of pathways into the overall biology of the clostridia.

Plasmids and bacteriophages are commonly found in clostridia, particularly in pathogenic species. Although most plasmids encode unknown (cryptic) functions, some have been demonstrated to possess genes for toxins and antibiotic resistance. Bacteriophages are widespread in pathogenic and industrial strains of clostridia. In certain pathogens, phages carry genes for toxins that can be transferred to normally nonpathogenic clostridia by infection. Phage infection and culture lysis have been a continual problem of clostridial cultures used for solvent production. Strain degradation and the loss of capacity of clostridia to produce high yields of solvents have also been problematic for industrial processes.

Medical Importance and Industrial Applications of Clostridia

Several clostridial species are of medical and industrial importance (Table 1). Many species are pathogenic to humans and animals, mainly through the production of protein toxins, enzymes, and virulence factors during infection. Other species have beneficial aspects in biotechnology, such as production of valuable metabolites, formation of enzymes catalyzing bioconversions, secretion of enzymes and proteins that convert wastes to higher value products, and formation of enzyme systems that metabolize pollutants or detoxify xenobiotics under anaerobic conditions (Table 1). One of the most remarkable applications of the clostridia in industrial microbiology is the utilization of botulinum neurotoxin for the pharmacological treatment of a diversity of human disorders characterized by involuntary or hyperactive muscle movements. The practical significance of clostridia to humankind is summarized in Table 1.

Table 1 Significance of clostridia in human welfare

Property or role	Important products and species
Ancient dyeing	Indigo formation by <i>Clostridium isatidis</i>
Cause of disease in humans and animals, for example, tetanus, botulism, gas gangrene, wound infections, enteric infections, blackleg, malignant edema	Various toxins are virulence factors including neurotoxins, cytotoxins, collagenases, lipases, lecithinases, DNases, RNases, ADP-ribosyltransferases, hyaluronidases, hemolysins, and other protein toxins produced by toxigenic <i>Clostridium</i> spp. including <i>C. tetani</i> , <i>C. botulinum</i> , <i>C. perfringens</i> , <i>C. difficile</i> , <i>C. histolyticum</i> , and <i>C. septicum</i>
Production of solvents and organic acids	Production of various acids, alcohols, and gases by various clostridia, particularly <i>C. acetobutylicum</i> , <i>C. beijerinckii</i> , <i>C. butyricum</i> , <i>C. pasteurianum</i> , <i>C. propionicum</i> , and <i>C. sporogenes</i> . Products include acetic acid, propionic acid, lactic acid, butyric acid, ethanol, acetone, 2-propanol, 1, 2-propanediol, 1,3-propanediol, and butanol
Food spoilage	Several clostridia cause various types of food spoilage. <i>C. tyrobutyricum</i> and <i>C. butyricum</i> cause gaseous spoilage of cheeses. Several species of psychrotrophic clostridia cause gas formation in vacuum-packaged chilled meats and certain other food products. Thermophilic clostridia including <i>C. bifermentans</i> and <i>C. nigrificans</i> cause thermophilic sulfide spoilage of canned foods or foods in tropical environments. Clostridia growing at acid pH conditions such as <i>C. pasteurianum</i> , <i>C. butyricum</i> , and <i>C. thermosaccharolyticum</i> can lead to gaseous spoilage of canned and pouched products
Source of industrial enzymes	Clostridia produce a variety of enzymes that are important industrially. These include polymer-degrading enzymes such as cellulases, amylases, pectinases, proteinases, and collagenases. Many of these enzymes have high thermal stability. Important clostridial species as sources of enzymes include <i>C. thermocellum</i> , <i>C. thermosulfurogenes</i> , <i>C. thermohydrosulfuricum</i> , and <i>C. thermosaccharolyticum</i> . Enzymes used in bioconversions and fine chemical syntheses as well as for the degradation of pesticides and xenobiotics are produced by <i>Clostridium</i> spp.
Source of pharmaceuticals and use in cancer therapy	Botulinum neurotoxin is produced by <i>C. botulinum</i> and has been used for the treatment of a variety of neurological disorders including dystonias, involuntary muscle disorders, pain, inflammatory syndromes and for cosmetic purposes. Certain clostridial species have been investigated for use in cancer therapy. The spores of clostridia target tumors, where they are able to proliferate in the malignant tissue. They produce native toxins or elicit compounds that are deleterious for tumor survival

Clostridial Diseases

Many clostridia cause devastating diseases of humans and animals. Known diseases produced by clostridia include botulism, tetanus, gas gangrene (clostridial myonecrosis), antibiotic-associated diarrhea and pseudomembranous colitis, foodborne diarrhea, necrotic enteritis of humans and domestic animals, and blackleg and malignant edema in cattle and sheep. Recently, wound infections and botulism have been detected in intravenous drug users from spore contamination in the illicit drugs.

One of the most fascinating features of the clostridia is their production of a wide array of biologically active antigens, many of which cause diseases in humans and animals. About 20 clostridial species produce protein toxins that are lethal for animals and/or humans. Genomic analyses have supported that clostridia produce a number of virulence factors, especially a large variety of enzymes and toxins. The clostridia produce more types of protein toxins than any other bacterial genus. Some of the toxins are notable for their extreme potency; for example, botulinum and tetanus toxins are the most lethal poisons known. Botulinum toxin can be preformed in foods and cause a true intoxication, whereas most of the other pathogenic clostridia produce toxins and inflict damage during infection of the host.

Food Spoilage and Food Poisoning

The spores of clostridia are widespread in the environment and present in many foods. Spores from several species resist minimal food processing procedures, and they can later germinate and cause spoilage or safety problems in foods. Two clostridial species, *C. botulinum* and *C. perfringens*, are the major species causing food poisoning. Several other clostridial species can spoil foods by forming gas from organic acids or carbohydrates or by carrying out putrefactive degradation of food proteins. Recently, clostridia that grow at cold temperatures (psychrotrophic clostridia) have been increasingly involved in gas formation and organoleptic spoilage of several classes of foods.

Solventogenic Clostridia

Clostridia produce fermentation end products of industrial importance, including acetone, butanol, ethanol, 1,2- and 1,3-propanediol, acetate, and butyrate. The acetone–butanol fermentation process employing *C. acetobutylicum* was used for about 30 years on a large industrial scale, but due to economic constraints, these solvents are now mostly produced by chemical synthesis. Ethanol synthesis from thermophilic clostridia growing on waste feedstocks, such as cellulose, has attracted much interest, but the process is limited by low ethanol yields and formation of side products. Industrial interest in clostridial metabolites currently is focused on products that are difficult to prepare in good yields by chemical synthesis, such as chiral compounds.

Industrial Enzymes from Clostridia

Several thermophilic clostridia produce remarkably stable, highly efficient enzymes that selectively degrade inexpensive substrates, including cellulose, xylan, pectin, pullulan, collagen, and starch. These enzymes are being developed for industrial uses in food processing and production, in detergents, and for other applications. Proteases from clostridia are used for chillproofing of beer and for other applications in food processing. Clostridia also produce enzymes of value in bioconversions and in degradation of pollutants and xenobiotics. Thus, the clostridia appear to have important roles in environmental bioremediation.

Use of Clostridial Toxins as Pharmaceuticals

Botulinum neurotoxin is the most poisonous substance known on Earth. Botulinum toxin has become an extremely important pharmaceutical for more than 100 neurological disorders. Selective injection of botulinum toxin into nerve–muscle regions produces a local weakening of proximal muscles, providing relief from excessive involuntary muscle contractions and pain or disfigurement. Botulinum neurotoxin is also used for cosmetic enhancement of humans. The outstanding properties of botulinum toxin as a pharmacological agent is its extreme specificity for nerves and its long duration of action. Clostridial toxins or fragments of the entire toxins are being developed for drug delivery to the nervous system, prevention of food poisoning, prevention of inflammatory responses, and stimulation of the immune system. It is remarkable that nature's most poisonous substances are being employed as therapeutics to benefit humans.

Clostridia in Cancer Therapy

It has long been recognized that spores administered to animals localize in necrotic tissues and in tumors. This is mainly due to the anaerobic environment present in these tissues. The first attempt to use clostridia for the treatment of cancer in animals was reported in 1935. Currently, there is interest in enhancement of clostridial oncolysis to suppress growth or to kill tumors in humans, as well as in cancer diagnosis.

Conclusions

The clostridia are ancient evolutionary ancestors within the Gram-positive bacteria. Outstanding biological properties of this important group of bacteria include their strict anaerobic metabolism, the formation of resistant endospores, and the synthesis of a wide array of distinctive toxins and enzymes. Although clostridia have been known for centuries to cause devastating diseases in humans, such as tetanus, botulism, and gas gangrene, they also are a source of metabolites and enzymes that have considerable utility in biotechnology. Advances in our knowledge of ecology, metabolism, genetics, and genomics of clostridia promise to increase the biological understanding and appreciation of the clostridia, prevent dreadful diseases characteristic of the clostridia, and enhance their industrial utility to humankind.

Glossary

Attenuated (virulence) Reduced capacity to induce damage/disease.

Biofilm A structured community of microorganisms that adhere to each other and are commonly embedded within a self-produced extracellular matrix composed of polysaccharides, proteins, and DNA.

Candidiasis Infections caused by *Candida* species.

Colonization Growth (or prolonged survival) of microorganisms in a distinct (host) niche.

Commensal Microorganism that grows within a host without (negatively) affecting the host species.

Dysbiosis Disturbance of the microbiota leading to microbial imbalance and commonly reduced species diversity; often associated with increased abundance of a few taxa or species.

Filamentation The production of filamentous growth forms (hypha, pseudohypha).

Hypha Long filaments of connected fungal cells, characterized by directed growth at the tip, branching, parallel cell walls and the absence of constriction at the septa separating individual cells.

Hypha-associated Genes or proteins that are usually only expressed by hypha and not by yeast cells.

Inoculation Introduction of a microorganism into a host or growth medium.

Macronutrients Nutrients that provide energy, for example, carbohydrates and amino acids.

Microbiota Ecological community of commensal, symbiotic and pathogenic microorganisms found at a distinct site/within a distinct host niche.

Micronutrients Nutrients required by organisms throughout life in small quantities as necessary cofactors for metabolism, for example, trace minerals and vitamins.

Morphogenesis The process by which an organism develops its shape. In the context of *Candida* it usually refers to the formation of hypha from yeast cells, whereas the term “reverse morphogenesis” is sometimes used to describe the formation of yeast cells from filamentous growth forms.

Morphotype Morphological growth form; *C. albicans* has different morphotypes, for example, yeast, pseudohypha, and hypha.

Mycobiota Ecological community of fungi found at a distinct site/within a distinct host niche.

Nosocomial infection An infection contracted by a patient while under medical care.

Opportunistic infection An infection that usually does not occur in healthy hosts but only if predisposing factors (weakened immune system, breached epithelial barriers) are present that give the pathogen the opportunity to establish an infection.

Pathobiont A microorganism that under normal circumstances lives as a commensal but has the potential to cause disease.

Pathogen A microorganism that causes disease.

Pathogenesis The mechanisms leading to disease.

Pseudohypha Elongated fungal cells, characterized by constrictions between individual cells.

Pyroptosis A form of programmed cell death of immune cells that occurs most frequently upon infection with intracellular pathogens and leads to the release of proinflammatory cytokines, thereby contributing to inflammation.

Virulence factor Gene or attribute that contributes to the virulence of a pathogen.

Virulence The ability of microorganisms to cause damage to a host.

Commensal to Pathogen Transition of *Candida albicans*

Introduction: *Candida albicans* as Commensal and Pathogen

Candida albicans is an archetypical opportunistic pathogen: While it is the most common cause of systemic fungal infections, it is also carried by two out of three humans on mucosal membranes without causing any damage (Kett et al., 2011; Odds, 1987; Pfaller and Diekema, 2007; Richardson and Rautemaa, 2009; Thewes and Hube, 2008). As a commensal, the fungus is commonly found within the oral cavity, gastrointestinal tract (GI tract), and on the urogenital mucosa. On all sites, it has to adapt to the local environment that differs significantly between various anatomical locations. Environmental conditions are on the one hand defined by properties of the local mucosa. On the other hand, *C. albicans* has to establish its niche within the complex microbiota that also

This article is a reprint of Maria J. Niemiec, Mario Kapitan, Melanie Polke, Ilse D. Jacobsen, Commensal to Pathogen Transition of *Candida albicans*, Reference Module in Life Sciences, Elsevier, 2017.

varies depending on the anatomical site (Morgan et al., 2013). Adaptation to these different niches requires versatile nutrient acquisition, metabolic flexibility, and stress resistance.

C. albicans adaptability contributes to its success as an opportunistic pathogen. If the balance between host defense systems, microbiota, and *C. albicans* is disturbed, for example, due to immunosuppression, impairment of mucosal barrier integrity, or disturbance of the bacterial microbiota by antibiotics, *C. albicans* can cause both local and disseminated infections (Goncalves et al., 2016; Kullberg and Arendrup, 2015; Suleyman and Alangaden, 2016). Mucosal infections can occur at all sites that are colonized with *C. albicans* and are often associated with specific risk factors that do not predispose to infections at other sites: For example, oropharyngeal candidiasis is very common in AIDS patients but these patients do not have an increased risk for other forms of candidiasis (Fidel, 2011). Chronic mucocutaneous candidiasis is often associated with gene mutations that impair Th17 immunity. Even though these patients do suffer continuously from invasive local candidiasis, the exact kind of mutations in the IL-17 pathway determines whether they additionally have an increased risk for disseminated infection (Okada et al., 2016). These examples illustrate the complexity and niche specificity that applies to the host–pathogen interactions that control the commensal-to-pathogen shift in *C. albicans*.

In the following parts we will summarize the current knowledge on which features make *C. albicans* a successful commensal, focusing on the GI tract, and discuss some of the main attributes that contribute to its success as an opportunistic pathogen.

***Candida albicans* as a Commensal: Living With the Host and Microbial Neighbors**

As mentioned above, both the environmental conditions and the present microbiota vary between different mucosal sites. Consequently, different aspects of *C. albicans* physiology contribute to varying extend to fungal survival in the different mucosal niches. In the following part we focus on the GI tract; for further information on *C. albicans* as a commensal and pathogen in the oral and vaginal niche we refer the reader to recent comprehensive reviews (Cassone, 2015; Donders and Sobel, 2017; Goncalves et al., 2016; Hebecker et al., 2014; Lalla et al., 2013; Peters et al., 2014; Singh et al., 2014).

Fungal Factors That Contribute to *Candida albicans* Survival in the Human Gut

In the human body, the GI tract is not only the major reservoir of *C. albicans*, but also the dominant source for candidiasis, a life-threatening systemic infection caused by this yeast (Mittal and Coopersmith, 2014). Research in fact provides evidence that the majority of systemic *Candida* infections are endogenous, so patients are infected with their very own *C. albicans* strains (Miranda et al., 2009). As fungi were long underrepresented in microbiome studies due to technical reasons, the exact densities of fungi in the GI tract and other body niches are still poorly understood. However, there is increasing interest toward the entity of fungi living on and in the human body, termed mycobiota, and its interaction with the human host (Underhill and Iliev, 2014). In approximation, recent studies estimate at least 0.1% of all microorganisms (so 10^{11} out of 10^{14}) in the human GI tract to be fungi (Ianiro et al., 2016; Qin et al., 2010). In this context, it is interesting that *C. albicans* is among the few microbial species enriched in patients upon intensive care, while the overall microbial diversity under these circumstances is decreased (Zaborin et al., 2014). *Candida* colonization is also more common among patients with GI tract pathologies, like inflammatory bowel disease (IBD) or Crohn's disease (Kumamoto, 2011). Furthermore, antibiotic treatment, reducing the number of bacteria, is associated with increased fungal colonization (Underhill and Iliev, 2014). This indicates that *C. albicans* is well adapted to the GI tract and can grow to high densities if bacterial competition is reduced. As increased colonization with *C. albicans* constitutes a risk factor for candidiasis (Muskett et al., 2011), recent research increasingly focuses on the properties that allow the fungus to colonize mucosal surfaces and especially the gut (recently reviewed in Prieto et al. (2016)).

Within the length of the GI tract and across the diameter of the intestine, several environmental parameters, including pH, oxygen and nutrient availability, and concentrations of hydrolytic enzymes and antimicrobial peptides (AMPs), vary significantly (Khutoryanskiy, 2015; Zheng et al., 2015a,b). Some of these factors are interconnected: the pH for instance ranges from highly acidic in the stomach to alkaline in the small intestine. It influences availability of micronutrients, such as iron, the proton gradient, that is important for nutrient uptake, and affects the efficacy of fungal enzymes (Davis, 2009). *C. albicans* can grow within a broad pH range, mediated by the sensing of environmental pH via the plasma membrane receptors Rim21 and Dfg16. The associated signaling cascade leads to activation of the transcription factor Rim101 at neutral to alkaline pH. Other factors involved in the response to changing pH are the cell wall β -glycosidases Phr1 and Phr2, Mds3 and calcineurin. Additionally, *C. albicans* is able to actively increase the local pH by metabolizing amino acids or polyamines, leading to the production and release of ammonia (Vylkova et al., 2011). To which extend pH sensing and adaptation exactly contribute to survival of *C. albicans* in the gut has yet to be experimentally addressed.

Even though the GI tract might appear rich in nutrients, specific types of carbon and nitrogen sources can be scarce in distinct microniches (recently reviewed in Fischbach and Sonnenburg (2011), Flint et al. (2012)). Furthermore, *C. albicans* has to compete with other members of the microbiota for available nutrients. The metabolism of *C. albicans* is very versatile and the fungus can use a wide range of both carbon and nitrogen sources (Brown et al., 2014; Ene et al., 2014). Peptides, amino acids, sugars, and organic acids can be taken up by specific transporters and used to produce energy or as building blocks. As they commonly need to be released or extracted from macromolecules, *C. albicans* possesses a number of proteases and lipases to support nutrient liberation (Polke et al., 2015). Typically, those enzymes include secreted aspartic proteases (Saps), lipases (Lips), and Plb phospholipases as well as several enzymes for the degradation of polysaccharides (Klis and Brul, 2015).

Overall, the gene expression of *C. albicans* colonizing the mouse gut appears to be distinct from other profiles. By comparing *C. albicans* cells invading host tissue during disease with *C. albicans* colonizing the mouse cecum, interesting similarities were

revealed, but also niche- and mode-specific differences were detected (Rosenbach et al., 2010; Thewes et al., 2007; Walker et al., 2009; Zakikhany et al., 2007). The commensal gene expression profiles shared similarities with both, logarithmically growing cells and cells in stationary phase under standard in vitro conditions (Rosenbach et al., 2010). The glucose metabolism was induced even though the gut is considered to be a low-glucose niche (Rosenbach et al., 2010). Remarkably, although *C. albicans* grows predominantly as yeast in the mouse cecum (see also below), several genes that encode certain adhesins were also expressed despite that they were previously thought to be exclusively hypha-associated (Herwald and Kumamoto, 2014; Rosenbach et al., 2010).

So far, studies aiming at experimentally testing the contribution of factors to *C. albicans* fitness as a commensal of the GI tract have focused mainly on transcription factors (TFs) due to their central role for controlling expression of physiological traits. One well studied TF is Efg1 that is involved in filament formation (Stoldt et al., 1997). *EFG1*-deficient *C. albicans* strains are unable to form filaments under many in vitro conditions (Stoldt et al., 1997). In colonization experiments using mice, Efg1 influences *C. albicans* survival in the GI tract as *EFG1*-deficient strains were found to be more efficient colonizers of the mouse gut (Pierce et al., 2013). The stress response in the cecum was also induced in an Efg1-dependent manner (Pierce et al., 2013). Further TFs required for *C. albicans* filamentation under certain laboratory conditions and important for GI tract colonization are Cph2 and Tec1 (Rosenbach et al., 2010). Another transcription factor involved in the intestinal commensal state is Efh1, a paralog of *EFG1* whose deletion does not affect filamentation under in vitro conditions (Doedt et al., 2004). Efh1 appears to actively promote *C. albicans* commensalism but is dispensable for systemic infections (White et al., 2007). Using a signature-tagged mutagenesis approach, Pérez et al. tested a library of 77 TFs that did not affect growth in vitro to assess their ability to colonize the mouse gut. Thereby they identified six factors that contributed to colonization: *TYE7*, *RTG1*, *RTG3*, *LYS144*, *HMS1*, and *orf19.3625* (Pérez et al., 2013). *Rtg1*, *Rtg3*, *Tye7*, and *Lys144* affect expression of genes involved in nutrient acquisition and metabolism (Pérez and Johnson, 2013; Rosenbach et al., 2010). Furthermore, *C. albicans* mutants lacking the gene *PHO4*, encoding a transcription factor involved in phosphate metabolism, were outcompeted by the wild type during colonization (Urralde et al., 2016). These results thus underline the role of metabolic adaptation and nutrient acquisition for fitness in the gut. Finally, the kinase Hog1, a central factor in the general stress response of *C. albicans*, was shown to contribute to intestinal fitness (Prieto et al., 2014), indicating that *C. albicans* is exposed to stressful conditions in this environment.

The current knowledge implies that morphogenesis, metabolism and stress response affect *C. albicans* survival in the GI tract. This picture is certainly still incomplete and to which extent and by which mechanisms distinct pathways or factors contribute to fitness remains to be determined. Currently ongoing research will likely provide further information on distinct factors influencing the life of *C. albicans* as a gut commensal in the near future.

Morphology of *Candida albicans* in the Gut

One of the most remarkable features of *C. albicans* is its morphological flexibility (Noble et al., 2016). This includes growth as typical round, budding yeasts and filamentous growth either as long true hyphae or pseudohyphae. Both morphotypes are essential for virulence: Yeasts are highly proliferative and thought to be important for dissemination, while hyphae are important for invasion and tissue destruction (Gow et al., 2002; Jacobsen et al., 2012; Whiteway and Oberholzer, 2004). While yeasts, pseudohyphae, and hyphae are isolated from sites of infection, filamentous forms of *C. albicans* are found only rarely during gut colonization (Kayser, 2010; Noble et al., 2016; White et al., 2007). As the intestinal environment provides strong triggers for filamentation (e.g., 37°C, high CO₂, and peptidoglycan shed by bacteria) (Noble et al., 2016; Sudbery, 2011; Wang and Xu, 2008), the absence of prominent filamentation is unlikely due to a lack of hypha induction but more likely mediated by other environmental factors or influenced by the bacterial microbiota.

In addition to normal yeasts, also known as white α/α cells, a gut-specific yeast-like morphotype termed gastrointestinally-induced transition (GUT) was recently identified in this particular niche (Pande et al., 2013). GUT cells are phenotypically and metabolically distinct from other morphotypes and can be produced by passaging *C. albicans* through the murine GI tract. GUT cells are characterized by overexpressing *WOR1*, encoding a transcription factor that is not expressed in white cells and controls the white-opaque switching important for mating (Huang et al., 2006). However, GUT cells are distinct from mating-competent opaque cells and remain heterozygous at the mating type locus. Compared to other yeast forms, GUT cells have an elongated shape with smooth surface leading to altered colony morphology. GUT cells outcompete white cells in murine colonization, possibly due to an adapted metabolism that facilitates highly efficient utilization of the nutrients available in the gut (Pande et al., 2013).

Animal Models Used to Investigate *Candida albicans* Commensalism in the Gut

Currently, our knowledge on specific factors required for commensalism in the gut is still limited and nearly exclusively deduced from studies in mice, and a few studies in rats (Koh, 2013). Still, there are significant differences between humans and mice that need to be kept in mind when transferring knowledge from one organism to the other. Differences that might influence pathogenesis of infections are, for example, the composition of blood leukocytes, the functionality of neutrophils, or the inflammatory response (Ermet et al., 2013; Mestas and Hughes, 2004; Seok et al., 2013; Warren, 2009). At the commensal state of *Candida*, there are also some factors to be considered when mimicking men in mice. Laboratory mice are usually not colonized with *C. albicans*, even though other *Candida* species such as *Candida krusei* can be present (Dollive et al., 2013). This might point to a distinct role of the murine gut microbiota mediating colonization resistance toward *C. albicans*. However, differences in exposure might also affect these findings. Laboratory mice kept under hygienic conditions are probably more likely to harbor

environmentally-derived yeasts (such as *C. krusei*) than *C. albicans* that is only found associated with warm-blooded hosts (Odds, 1987). Furthermore, timing of exposure might be relevant. Humans are believed to be colonized during birth or the first days of life when the gut microbiota is in its earliest stages. Indeed, also infant mice are more susceptible both to colonization and spontaneous dissemination of *C. albicans* (Guentzel and Herrera, 1982; Pope et al., 1979). Furthermore, food composition affects colonization resistance (Gunsalus et al., 2016; Kadosh et al., 2016).

In general, however, many studies have shown that the gut microbiota of adult mice and other rodents mediates colonization resistance toward *C. albicans* (Kennedy and Volz, 1985a,b; Koh, 2013). Therefore, depletion of bacteria is necessary to facilitate stable colonization of adult mice with *C. albicans* (see Fig. 1). Experimental procedures published in different studies vary in the choice of antibiotics and *C. albicans* inoculation regimen (selected recent examples in Table 1), but mutually a combination of antibiotics is used. The infectious dose appears to have less influence on long-term colonization as proliferation to high, stable colonization levels occurs within a few days, even after inoculation of a minimal dose of 100 *Candida* cells (Prieto and Pla, 2015). Importantly, colonization experiments with single *C. albicans* mutants might not always reveal the influence of genes on colonization efficiency and competition experiments might be required to detect fitness defects (Prieto et al., 2014).

According to our current understanding, *C. albicans* generally does not spontaneously disseminate in significant numbers from the gut to the blood stream of adult mice (Ekenna and Sherertz, 1987; Koh, 2013). In order to achieve translocation and disseminated infection, impairment of the epithelial barrier and suppression of the innate immune system are required

Experimental set-up for *C. albicans* colonization and dissemination from the mouse gut

Fig. 1 Set-up for *Candida albicans* colonization and dissemination from the mouse gut. Widely-used experimental strategies to reduce the preexisting microbiota (blue), to colonize with *C. albicans* (*C.a.*, green), and to induce dissemination (orange) from the mouse gut. Illustration by I.D. Jacobsen.

Table 1 Overview of colonization strategies with antibiosis prior to *Candida albicans* inoculation of mice

Antibiosis	Inoculum	C. a. strain	CFUs/g feces	Time point p.i.	References

(Koh et al., 2008). This can be achieved, for example, by induction of colitis using the detergent dextran sulfate sodium and selective depletion of neutrophils. Alternatively, treatment with cyclophosphamide, a chemotherapeutic drug leading to the death of fast-proliferating cells, results in a combination of both, reduced barrier function of the enteric epithelium and immunosuppression via leukopenia (see Fig. 1). Consequently, mice treated with cyclophosphamide are more likely to develop disseminating candidiasis originating from the gut (Ekenna and Sherertz, 1987). Murine sepsis models based on mechanical disruption of the gut, such as cecal ligation and puncture, are not commonly used as a model for gut-derived candidiasis (Toscano et al., 2011; Warren, 2009), but might be an alternative approach. A typical experimental set-up for a colonization-dissemination experiment as currently used in the field is depicted in Fig. 1.

Candida albicans as Part of the Microbiota

In addition to immunosuppression and breach of mucosal barriers, the disturbance of the microbiota constitutes a major risk factor for disseminated candidiasis. Long-term antibiotic treatment and malnutrition during intensive medical care are prominent causes of dysbiosis (Zaborin et al., 2014). This indicates that the *C. albicans* population in the gut is usually controlled by commensal bacteria and possibly other fungi colonizing the respective niche in the body. This is mirrored in mouse models of *Candida* gut colonization: As mentioned above, extensive antibiosis prior to introduction of the fungus is necessary to achieve stable colonization with *C. albicans* (Fan et al., 2015; Koh, 2013). Like the bacterial microbiota, the fungal “mycobiota” is more and more appreciated for its immune-modulatory properties, and not only as a source of infection (Gouba and Drancourt, 2015; Suhr and Hallen-Adams, 2015; Underhill and Iliev, 2014). To date, little is known about the exact mechanisms of microbial competition and microbe–microbe interaction and microbe–host cross-talk and how this affects host health and disease development. Yet, recent research provides evidence for an intricate interplay of many actors that exceeds simple competition for resources.

Notably, interactions between microbes are numerous and occur naturally on all surfaces of the human body, i.e., the skin, the lung, the oral cavity, the urogenital tract and the GI tract (Peleg et al., 2010; Peters et al., 2012). The specific nature of these interactions varies depending on the species involved, but it can be expected that some general concepts are conserved. To date only few studies have specifically addressed the interactions of *C. albicans* with intestinal bacteria. Here, we will briefly summarize the current knowledge on *Candida*-bacteria interplay in general (for more detailed information we refer to Polke et al. (2015)).

Candida and bacteria can interact by (1) direct physical contact, (2) communication via released molecules, and (3) indirectly by modification of the environment and the host response. Given the high density of microorganisms on mucosal surfaces, direct contact is highly anticipated. Interestingly, different bacteria have been described to form aggregates with *C. albicans* and are often found to bind fungal hyphae better than yeast cells (Adam et al., 2002; Bagg and Silverwood, 1986; Bamford et al., 2009; Brand et al., 2008; Harriott and Noverr, 2010, 2011; Holmes et al., 1996; Jenkinson et al., 1990; Kong et al., 2015; Metwalli et al., 2013; Peters et al., 2010; Schlecht et al., 2015; Shirliff et al., 2009). Binding can involve both *C. albicans* and bacterial adhesins as well as mannosylation of fungal surface proteins (Bamford et al., 2009; Brady et al., 2010; Dutton et al., 2014; El-Sabaeny et al., 2000; Holmes et al., 1996; Klotz et al., 2007; Kong et al., 2015; Schlecht et al., 2015; Silverman et al., 2010; Tati et al., 2016; Wright et al., 2013). In the oral cavity, these interactions can promote *C. albicans* colonization and persistence (Cannon and Chaffin, 2001; Shirliff et al., 2009). Furthermore, adhesion to invading *C. albicans* hyphae can aid bacteria that otherwise would be unable or little efficient to penetrate host cells, as it has been shown for *Staphylococcus aureus* (Alves et al., 2014; Kong et al., 2015; Schlecht et al., 2015). Synergistic interactions of *C. albicans* and bacteria are also found in mixed-species biofilms, an important source of nosocomial infections (Hirota et al., 2017; Shirliff et al., 2009; Taff et al., 2013). Bacteria, including species present in the gut such as *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, *Enterococcus faecalis*, or *Salmonella typhimurium*, have been found to also affect filamentation of *C. albicans*, an effect often mediated by small, secreted signaling molecules (Brand et al., 2008; Cruz et al., 2013; Hogan et al., 2004; Kim and Mylonakis, 2011; Peleg et al., 2008; van Leeuwen et al., 2016). Most of these interactions negatively affect hypha formation and it is thus tempting to speculate that it is the microbiota that keeps *C. albicans* in the less invasive yeast form in the gut (Förster et al., 2016). Reducing bacterial microbiota by antibiotics might relief this restriction and thereby promote filamentation and invasion; however, this hypothesis has not been tested experimentally yet. These examples illustrate that *Candida*-bacteria interactions can be considered antagonistic, and therefore beneficial for the host, or mutualistic and thereby detrimental for the host (Förster et al., 2016; Polke et al., 2015).

Recent studies indicate that the human gut microbiota is very diverse with more than 1000 bacterial species and up to 75 fungal genera described (Mar Rodríguez et al., 2015; Qin et al., 2010). It furthermore becomes increasingly clear that a balanced composition of bacteria and fungi is associated with intestinal health, while dysbiosis is accompanied by a range of diseases (Lagunes and Rello, 2016; Mittal and Coopersmith, 2014; Sokol et al., 2016; Wheeler et al., 2016). The composition of the microbiota affects *C. albicans* survival in the gut and nonpathogenic gut-residing bacteria, i.e., Firmicutes and Bacteroidetes, that are involved in maintaining *C. albicans* colonization resistance in mice (Fan et al., 2015). One specific member of this group, *Bacteroides thetaiotamicron*, was demonstrated to mediate this effect by inducing the production of host antimicrobial effectors (Fan et al., 2015). Another group of bacteria with antagonistic relations to *C. albicans* are lactobacilli. Lactobacilli negatively affect *C. albicans* colonization by direct mechanisms, modification of the environment, and indirectly via cross-talk with host cells (Kelly et al., 2015; Noverr and Huffnagle, 2004; Romani et al., 2015; Wynne et al., 2004). While not being the only source, lactobacilli are known for their capacity to produce short-chain fatty acids (SCFAs) in the gut. SCFAs were demonstrated to increase barrier function of the gut epithelium and inhibit *C. albicans* filamentation (Kelly et al., 2015; Noverr and Huffnagle, 2004) and this mechanism might also contribute to colonization resistance and yeast growth.

Notably, while *C. albicans* is clearly affected by bacteria in the gut, the fungus likewise affects composition of the bacterial community and bacterial virulence. In mice, the introduction of *C. albicans* affects the composition and development of the microbiota after antibiotic depletion, leading to an enrichment of *Bacteroidetes* and *E. faecalis*, but slower regrowth of lactobacilli (Erb Downward et al., 2013). *C. albicans* furthermore dampens the virulence of *P. aeruginosa* in a colonization-dissemination model by reducing the expression of bacterial virulence factors (Lopez-Medina et al., 2015). In addition, *C. albicans* was also shown to promote growth of obligate anaerobic *Clostridium* spp. under aerobic conditions, potentially boosting their ability to colonize the human gut (Fox et al., 2014; van Leeuwen et al., 2016). While we are just at the beginning of unraveling the triangle of *C. albicans*, gut-residing bacteria and the human host, these findings indicate that bacterial–fungal interactions affect not only the composition of the microbiota but might also significantly influence the development of either bacterial or fungal infections.

Features That Contribute to the Success of *Candida albicans* as Pathogen

Virulence is a multifaceted feature of microorganisms that includes the ability to thrive within host tissue, withstand rapid elimination by the immune system and the capability to cause tissue and/or organ damage. Keeping this in mind, it is not surprising that genes involved in various processes, from basic cell biology to specific interactions with host cells, have been demonstrated to affect the virulence potential of *C. albicans* (see (da Silva Dantas et al., 2016) for an overview). Here, we will focus on factors that influence the interaction of the fungus with host cells, nutrient acquisition and we will briefly discuss the role of the cell wall and morphogenesis for candidiasis.

Interaction of *Candida albicans* With Epithelial Cells

As a commensal *C. albicans* lives in close contact with – or depending on the presence of a mucus layer, in proximity to – epithelial cells without causing overt damage. This changes during infection characterized by increased fungal load, invasion into epithelial barriers (and underlying tissue), induction of an immune response and tissue damage. The factors that trigger the transition from commensalism to infection are only incompletely understood, but the disturbance of the microbiota clearly plays an important role (Fan et al., 2015; Lopez-Medina et al., 2015) and recently reviewed in Förster et al. (2016) and Höfs et al. (2016).

The first step toward infection is attachment of yeasts to host cells, in case of mucosal membranes epithelial cells (Fig. 2). This complex process is likely initiated by passive forces, for example, hydrophobic cell–cell interactions, followed by specific

Fig. 2 Adhesion, invasion, and damage by *Candida albicans* in the human gut. Major steps of the *C. albicans* life cycle during the switch from commensal to pathogen. Hyphae-associated adhesins (blue anchors) mediate the attachment to enterocytes. Growing hyphae and subsequent release of candidalysin, proteases (orange scissors) and lipases penetrate the enterocyte barrier and destroy underlying cell layers. Illustration by M.J. Niemiec and M. Polke.

interactions between fungal and host cell surface molecules (a comprehensive overview has recently been published by Moyes et al. (2015)). While some adhesins also occur on yeast cells, hyphae express adhesins, like Als3 and Hwp1, in larger number and more efficiently (Phan et al., 2007; Wächtler et al., 2011). Targeted host structures include cadherins, integrins and components of the extracellular matrix (Chaffin, 2008; Phan et al., 2007; Zhu et al., 2012). Of note, adhesion to host cells is a strong trigger of filamentation in vitro and hypha formation is important for the second step during infection: invasion (Fig. 2). Invasion into host cells occurs by two mechanisms, induced endocytosis and active penetration. Active penetration is a fungal-driven process that requires directed filamentous growth (Wächtler et al., 2012). The current knowledge suggests that in addition to physical forces provided by the turgor pressure, hydrolytic enzymes, especially Saps, support this process. Inhibition of aspartic proteases by pepstatin A significantly reduces invasion (Dalle et al., 2010); the contribution of individual Saps to this process is however still controversially discussed (Naglik et al., 2008, 2003). In contrast to active penetration, induced endocytosis requires the activity of host cells and occurs even with inactivated fungal cells. It is initiated by the recognition of distinct fungal surface proteins (“invasins”) by host cell receptors, which triggers rearrangement of the cytoskeleton leading to uptake of the fungal cell. The first *C. albicans* invasin identified was Als3 that binds to cadherins on host cells (Phan et al., 2007). Another known *C. albicans* invasin is Ssa1 and further host receptors include the EGF receptor and the human epidermal growth factor receptor 2 (Sun et al., 2010; Zhu et al., 2012). Importantly, as Als3 is a hypha-specific protein, both active penetration and induced endocytosis depend largely on hypha formation. Therefore, hyphae are considered to be the invasive morphology in *C. albicans*.

Invasion is a prerequisite for damage but not necessarily linked to damage of host cells: As the host membrane remains intact following initial invasion, forming a glove-like structure surrounding growing hyphae (Wächtler et al., 2012; Zakikhany et al., 2007), the host cell is not immediately lysed. Indeed, specific *C. albicans* mutants have been identified that show unaltered adhesion and invasion but significantly reduced damage in the interaction with epithelial cells. One of these mutants is *C. albicans eed1Δ/Δ*, lacking *EED1*, a factor that is essential for maintenance of hyphal growth and thus hyphal elongation. Following invasion, this mutant reverts back to yeast growth intracellularly, thereby reducing the strain on the host cell membrane afflicted by growing hyphae of wild type *C. albicans* (Martin et al., 2011; Zakikhany et al., 2007). Other examples are mutants lacking either *DUR31* or *HSP21*, that likewise show reduced hyphae formation following invasion (Mayer et al., 2012a,b). Most important, however, was the discovery that an *ECE1* deletion mutant is highly attenuated in epithelial damage, despite normal filamentation. *ECE1* was already identified in the 1990s as one of the genes most highly expressed by hyphae compared to yeast cells (Birse et al., 1993). Yet, its function was only elucidated in 2016 (Moyes et al., 2016): *ECE1* encodes a protein that is cleaved into eight short peptides by Kex2. Peptide 3 generated by this cleavage adopts an α -helical structure and integrates into host cell membranes, leading to permeabilization and lysis. Due to this effect, the peptide was named candidalysin (Moyes et al., 2016). Thus, candidalysin links hyphal morphology and damage beyond physical rupture by continuous filamentous growth and provides further explanation for the significant role of filamentation in pathogenesis (Wilson et al., 2016).

Interaction of *Candida albicans* With the Immune System

Immune cells are rapidly recruited during candidiasis and especially innate phagocytes are efficient and essential effector cells during fungal infections (Fig. 3; Duggan et al., 2015; Lionakis, 2014; Lionakis et al., 2011). In fact, impairment of the immune system represents a risk factor for candidiasis, but not all patients suffering from disseminated *C. albicans* infections are perceptibly immunocompromised (Guery et al., 2009; Nolla-Salas et al., 1997; Yapar, 2014). To be a successful pathogen, *C. albicans* needs to be able to either prevent recognition or survive antimicrobial mechanisms employed by immune cells to a certain extent. As the immune response to *C. albicans* is addressed in detail in another module of this series, we will focus here on some of the mechanisms by which the fungus withstands elimination of the immune system.

The immune system can be roughly divided into cellular and humoral effector mechanisms. Humoral factors include antibodies, the complement system, and AMPs. Antibodies are readily produced in humans and mice following exposure to *C. albicans* (Mochon et al., 2010; Pitarch et al., 2006, 2009, 2011) but naturally induced antibodies are considered to have only a limited protective effect (recently reviewed in Richardson and Moyes (2015)). The complement system and AMPs are evolutionary old and comprise two of the first lines of defense against invading microbes. Furthermore, AMPs are produced by mucosal epithelial cells even in the absence of a pathogenic threat and thereby control the commensal microbiota. Several AMPs, β -defensins, the cathelicidin LL-37, and histatin 5, have been shown to kill *C. albicans* in vitro (Chang et al., 2012; Vylkova et al., 2007a,b). It has furthermore been proposed that the reduced levels of histatin 5 observed in the saliva of HIV⁺ patients contribute to the increased risk of these patients for oropharyngeal candidiasis (Khan et al., 2013). Although this and the hypothesis that AMPs control fungal growth on mucosal surfaces in vitro appear plausible, they still need to be experimentally verified. Nonetheless, *C. albicans* also seems to have evolved AMP resistance mechanisms, like inactivation through proteolytic cleavage of AMPs by Sap9 and Sap10 and inactivation by a secreted glycodomain of Msb2 (Meiller et al., 2009; Puri et al., 2012; Swidergall et al., 2013; Szafranski-Schneider et al., 2012). Tolerance to AMPs can furthermore be induced by induction of compensatory mechanisms, for example, Pbs2 via the Hog1 stress response pathway, or stabilization of mitochondrial integrity via Ssd1 and Bcr1 (Argimon et al., 2011; Jung et al., 2013). Similarly, *C. albicans* interferes with complement activation by various means (recently reviewed in Cheng et al. (2012), Luo et al. (2013)), including proteolytic cleavage of active complement components by Saps and binding of host factors that regulate complement activation. To which extent these immune evasion mechanisms contribute to pathogenesis is not fully clear; however, complement defects render mice more susceptible to systemic candidiasis (Ashman et al., 2003; Tsoni et al., 2009). Furthermore,

Fig. 3 Killing of *Candida albicans* by professional human phagocytes. Killing of *C. albicans* by neutrophils and macrophages occurs intra- and extracellularly (IC/EC). IC: internalization of *Candida* via phagocytosis leads to inactivation of fungus by ROS (yellow lightning) and host effector proteins. EC: chemokines are released (purple glow) by activated phagocytes to recruit more phagocytes. Antifungal effector proteins are released into cell environment during degranulation. Neutrophils release extracellular traps (NETs) to entangle and kill *Candida*. Notably, *C. albicans* can outgrow macrophages, not neutrophils. Illustration by M.J. Niemiec.

opsonization by complement enhances phagocytosis and fungal killing (reviewed in Rambach and Speth (2009)), thereby linking complement evasion to other survival strategies of *C. albicans*.

Professional phagocytes, especially neutrophils and monocytes/macrophages, constitute cellular components of the first line of defense against *C. albicans* (Basu et al., 2008; Kullberg et al., 1999; Romani et al., 1996; van't Wout et al., 1988; van Enckevort et al., 1999). Following recognition of the fungus via interaction of pattern recognition receptors (PRRs) with fungal surface components acting as pathogen-associated molecular patterns (PAMPs) (recently reviewed in Erwig and Gow (2016), Miramon et al. (2013), Plato et al. (2015)), immune cells become activated and either phagocytose the pathogen or, in the case of neutrophils, can undergo degranulation or form neutrophil extracellular traps (NETs) via programmed cell death to release antifungal effector molecules (Gazendam et al., 2016; Stephenson et al., 2016; Fig. 3). The cell wall composition and, more importantly, exposure of distinct components on the surface significantly influences the efficacy of recognition and the subsequent response induced; thus, cell wall modifications are one way by which *C. albicans* can influence recognition by phagocytes and, additionally, phagosome maturation (Bain et al., 2014; Lewis et al., 2012). These mechanisms are discussed in detail below.

Phagocytosis requires physical uptake of the pathogen and is therefore influenced by size and shape. *C. albicans* hyphae can grow to a length that prevents complete phagocytosis (reviewed in Erwig and Gow (2016)). Therefore, the ability of *C. albicans* to form filaments affects the interaction with phagocytes. However, yeast cells can readily be phagocytosed and phagolysosome maturation in macrophages creates a hostile environment characterized by reduced pH, a high concentration of AMPs, reactive oxygen and nitrogen species (ROS and RNS, respectively), hydrolytic enzymes and nutrient starvation (Erwig and Gow, 2016; Miramon et al., 2013). *C. albicans* is able to escape from macrophages by either triggering pyroptosis, a programmed cell death pathway, or by affecting phagolysosome maturation, development of long hyphae, and physical piercing of macrophages. The exact mechanisms by which *C. albicans* triggers pyroptosis are only incompletely understood, but include neutralization of the phagosome by ammonia excretion, hypha induction, and remodeling of the cell wall associated with increased 1,3 β -glucan exposure (Uwamahoro et al., 2014; Vylkova and Lorenz, 2017; Wellington et al., 2014). The production of ammonia is intimately linked to amino acid metabolism and depends on the transcription factor Stp2, which controls expression of amino acid permease genes (Vylkova and Lorenz, 2014). Amino acids serve to generate ammonia, which is then excreted by Ato5 and neutralizes the phagosome (Danhof and Lorenz, 2015). As alkalisation in turn promotes filamentation (Vylkova et al., 2011), this process might link induction of pyroptosis and active escape via hyphal growth.

Professional phagocytes typically produce significant amounts of ROS and RNS upon encountering *C. albicans* and these oxidative mechanisms are important for killing of *C. albicans* (Aratani et al., 2002; Brothers et al., 2013; Sasada et al., 1987; Vazquez-Torres et al., 1996). The fungus responds by activating a general stress response that involves the protein kinase Hog1 and the more specific oxidative and nitrosative stress response pathway involving the TFs Cap1 and Cta4, respectively (Alonso-Monge et al., 2003; Arana et al., 2007; Brown et al., 2009; Chiranand et al., 2008; Patterson et al., 2013; Smith et al., 2004;

Wang et al., 2006). The activated stress response results in increased expression of detoxification systems (reviewed in detail in Dantas Ada et al. (2015), Erwig and Gow (2016), Miramon et al. (2013)) that include superoxide dismutases (SODs) (Frohner et al., 2009; Hwang et al., 2002; Miramon et al., 2012), catalase 1 (Nakagawa et al., 2003; Wysong et al., 1998), a glutathione-based system including glutathione peroxidases and reductases (Chaves et al., 2007; Enjalbert et al., 2007; Fradin et al., 2005; Miramon et al., 2014; Rubin-Bejerano et al., 2003; Yadav et al., 2011), and flavodoxin-like proteins (Li et al., 2015), that are protective against oxidative stress. Resistance against nitrosative stress depends on the flavohemoglobin NO scavenger Yhb1 (Ullmann et al., 2004). Upon phagocytosis, *C. albicans* furthermore upregulates certain metabolic pathways, including gluconeogenesis, enzymes for the utilization of alternative carbon sources, β -oxidation of fatty acids and the glyoxylate cycle, whereas glycolysis and protein synthesis are downregulated (Fradin et al., 2005; Lorenz et al., 2004). As the phagosome is generally considered to be poor in nutrients, this metabolic adaptation contributes to survival of the fungus in this specific environment (Fernandez-Arenas et al., 2007; Miramon et al., 2012). Finally, the upregulation of uptake systems for trace metals (discussed in detail below, see Fig. 4) by phagocytosed *C. albicans* cells likely contributes to overcome restriction of these micronutrients within host cells (Lorenz et al., 2004).

The Cell Wall as a Dynamic Factor in *Candida*–Host Interactions

As the outer layer of the cell, the cell wall and associated proteins present the structures that mediate contact of *C. albicans* with the environment and host cells. While on the one hand providing the major outer physical structure for the cell and mediating resistance to adverse environmental conditions, the cell wall is also presenting PAMPs that are recognized by PRRs on professional and associate immune cells (recently reviewed in Barreto-Bergter and Figueiredo (2014), Erwig and Gow (2016), Miramon et al. (2013), Plato et al. (2015)). Thus, the cell wall is critical for host–pathogen interactions of *C. albicans*. The fungal cell wall consists of different β -glucans, chitin and chitosan, which are located in an inner layer, and mannans attached to proteins in an outer layer (for details see (Free, 2013)). Most of the cell wall molecules are carbohydrates, which all contribute to immune recognition (reviewed in detail by Becker et al. (2015), Erwig and Gow (2016), Gow and Hube (2012), Netea et al. (2008), Plato et al. (2015), Zheng et al. (2015a,b)). The receptors involved in recognition and the response of immune cells differs depending on the cell wall moiety that is recognized: β -1,3 glucan interacts with the C-type lectin Dectin-1, which triggers a strong inflammatory response (Brown, 2011; Cheng et al., 2011). Mannans can be recognized by Toll-like receptors (TLRs), the Mannose Receptor (MR), DC-SIGN, Mincle and Galectin-3 (Barreto-Bergter and Figueiredo, 2014; Netea et al., 2008, 2006), likewise inducing a proinflammatory response which is, in comparison to β -1,3 glucan, less pronounced (Gow and Hube, 2012). Chitin is sensed by NOD2, TLR9 and the MR, but in contrast to the other components can reduce inflammatory responses (Mora-Montes et al., 2011; Wagener et al., 2014). Thus, the relative exposure of the different carbohydrates determines the quality and quantity of subsequent immune responses. This is exemplified in studies of *C. albicans* mutants with defects in mannosylation which lead to increased exposure of inner cell wall components, resulting in altered interaction with immune cells (reviewed in Hall and Gow, (2013)).

Importantly, the cell wall composition and relative exposure of the different carbohydrate components is highly dynamic and influenced by the morphological state, environmental conditions and the interaction with immune cells (recently reviewed in Hall (2015)). Yeast and hypha differ in the types of glucan (Lowman et al., 2003, 2014) and the amount of chitin, with chitin being more abundant in hypha (Munro et al., 1998). Furthermore, the distribution of chitin differs; while it is found along the cell wall of hypha, it is concentrated at the bud scar in yeast (reviewed in Gow et al. (2012)). Furthermore, some mannoproteins are differentially expressed depending on the morphology, for example, hypha-specific proteins like Hwp1 and Als3 (reviewed in Sundstrom (1999), Trevijano-Contador et al. (2016)), and the mannan composition in yeast and hypha is different (Shibata et al., 2007). As a consequence of these differences, immune cells respond differently to yeast and hypha (reviewed in more detail in Erwig and Gow (2016), Gow et al. (2011), Jacobsen et al. (2012), Trevijano-Contador et al. (2016)).

Fig. 4 Micronutrient acquisition by *Candida albicans*. *C. albicans* imports, stores, and exports trace elements during its life cycle. In the mammalian host, the availability of micronutrients is limited. Depicted are the transport systems for zinc and iron. Illustration by M. Kapitan.

The environment influences the cell wall composition and structure. Mannan structures (Ene et al., 2012; Kruppa et al., 2011; Lowman et al., 2011) and the levels of glucan and chitin (Ene et al., 2012), for example, vary depending on the culture conditions. Lactate induces active β -glucan masking while cell wall stress induced by the antifungal echinocandins leads to increased chitin and enhanced β -glucan exposure both in vitro and during in vivo treatment (Ballou et al., 2016; Lee et al., 2012; Walker et al., 2008; Wheeler et al., 2008). Importantly, in the absence of antifungals, unmasking of β -glucan also occurs during systemic candidiasis in mice as a result of active cell wall remodeling in response to damage by NETs (Hopke et al., 2016). Chitin can also be upregulated during infection, affecting recognition by Dectin-1, a phenomenon that varies between different *C. albicans* strains (Marakalala et al., 2013). Increased chitin in *C. albicans* is furthermore associated with reduced virulence in a systemic mouse model (Lee et al., 2012), highlighting the importance of the cell wall and its dynamic modifications for the interactions *C. albicans* with its host.

The Influence of Macronutrients on *Candida*–Host Interaction

As both a commensal and a pathogen, *C. albicans* can thrive at different anatomical sites. These differ not only in pH, oxygen levels, and host defense systems but also regarding the quality and quantity of available carbon and nitrogen sources. Its success at the different niches suggests that *C. albicans* is metabolically versatile and has evolved means to assimilate nutrients from a range of sources. Furthermore, the dissemination into various tissues during systemic infection requires fast adaptation to local nutrient availability. Indeed, *C. albicans* can utilize a vast variety of different sugars and amino acids (Brunke and Hube, 2013) and a range of secreted hydrolytic enzymes contributes to the liberation of nutrients from complex molecules (Brunke and Hube, 2013; Naglik et al., 2004; Schaller et al., 2005). Complex regulatory networks mediate the response of *C. albicans* to nutrient starvation or alterations in the available carbon or nitrogen sources, leading to altered expression of hydrolases, transporters, and metabolic pathways like gluconeogenesis, glycolysis, or fatty acid β -oxidation (Askew et al., 2009; Barelle et al., 2006; Lee et al., 2013; Morschhauser, 2011; Ramachandra et al., 2014; Sabina and Brown, 2009). In comparison to the related baker's yeast *Saccharomyces cerevisiae*, substantial transcriptional and posttranslational rewiring has occurred in *C. albicans*, contributing to the metabolic flexibility of *C. albicans* (Ramirez and Lorenz, 2007; Sandai et al., 2012; Whiteway et al., 2015).

In addition to providing the necessary energy for fungal survival, growth, and production of effector molecules, metabolic adaptation is directly linked via transcriptional networks to the expression of different fitness and virulence attributes such as morphogenesis, stress resistance, adhesions, and hydrolytic enzymes (Han et al., 2011). Cell wall composition is also influenced by nutrients, especially carbon metabolism, and thereby metabolism indirectly influences the interaction with immune cells (recently reviewed in Hall (2015)). One well studied example is the growth of *C. albicans* on lactate in comparison to glucose and the changes caused by this. While most growth media used in the laboratory are rich in glucose, glucose availability is limited within the host. Thus, *C. albicans* has to use alternative carbon sources such as lactate. Growth on lactate in vitro led to alterations in cell wall architecture and secretome, with consequences for adhesion, stress resistance, and interaction with immune cells: Lactate grown cells were phagocytosed less by macrophages while fungal escape was enhanced; at the same time lactate-grown *C. albicans* cells induced more IL-10 but less IL-17, thereby leading to a reduced proinflammatory response (Ene et al., 2012, 2013). As a consequence, fitness of lactate-grown *C. albicans* cells in vivo was enhanced (Ene et al., 2012).

Due to the link between metabolism and fitness/virulence traits, the adaptation of *C. albicans* to different environments and nutrient availability within the host simultaneously affects expression of virulence factors (recently reviewed in Brown et al. (2014)). This linkage of metabolic responses to environmental clues and virulence can be interpreted as “adaptive prediction” (Mitchell et al., 2009), by which the availability of distinct nutrients serves as a clue for further subsequent environmental changes, for example, attack by immune cells following translocation into the blood stream, leading to oxidative stress due to ROS production. From an evolutionary perspective, this linkage is likely to be highly advantageous to the fungus and likely contributes to its success in diverse anatomical niches both as a commensal and a pathogen. For more information and a summary of the open questions, we refer the readers to the review by Brown et al. (2014).

Acquisition of Micronutrients by *Candida albicans*

Micronutrients are as essential for microbial growth as carbon- and nitrogen sources. Trace metals such as iron, zinc, copper and manganese are essential cofactors in enzymes and stabilize three-dimensional protein structures (Palm-Espling et al., 2012; Waldron et al., 2009). However, their free availability in the host is limited by sequestration and binding to host molecules. Host-mediated nutrient depletion from invading pathogens is also termed “nutritional immunity,” a mechanism that has gained increased attention in recent years, and is therefore described in some detail below.

Every aspect of nutritional immunity, from the host or pathogen perspective, reflects the coevolutionary nature of these interactions. Best studied is the competition for iron, but most concepts apply to all transition metals in eukaryotes (Sutak et al., 2008; Weinberg, 1975). In the host, iron is mainly kept intracellular – free iron is practically unavailable in blood or other extracellular liquids, with exception of the gut lumen. Iron is bound to transferrin in plasma and lactoferrin in external secretions. However, in order to grow within the host, microbial pathogens cope with these limitations using different strategies: In case of direct physical contact between the host iron source and the pathogen, host iron-retaining proteins might be manipulated to release their iron load into the extracellular environment for uptake. Secondly, many bacteria and fungi secrete siderophores: Small

molecules with exceptionally high iron affinity that free iron from host proteins followed by resorption into the pathogen cell. In response, mammals produce lipocalin-2 to intercept siderophores. This can in turn be counteracted by many pathogens which disguise their siderophores by glycosylation (Sutak et al., 2008). Iron is a common cofactor in enzymes and one of the most important direct functions of iron during host–pathogen interactions is likely the detoxification of H_2O_2 by the iron-dependent heme-enzyme catalase (Hamilton and Holdom, 1999). Iron uptake in *C. albicans* occurs by reductive and nonreductive mechanisms (Almeida et al., 2009; Waldron et al., 2009; Fig. 4). In a nutshell, the high affinity reductive uptake system functions via the interplay of three enzymes. A reductase (Fre) converts ferric Fe^{3+} to ferrous Fe^{2+} . The actual uptake is mediated by a permease (Ftr) and a multicopper ferroxidase (Fet). *C. albicans* relies on this pathway to acquire iron from ferritin and transferrin (Almeida et al., 2008; Knight et al., 2005). Probably due to functional redundancy due to gene expansion of the reductases and multicopper oxidases, only the permease Ftr1 has been shown to be crucial in blood stream infections by *C. albicans*. Nonreductive iron uptake is based on the import of iron-containing proteins, namely hemoglobin and siderophores. *C. albicans* has receptors for heme (e.g., Rbt5), but also for ferritin (reductive uptake). The ferritin receptor and adhesin Als3 is expressed only by hyphae (Almeida et al., 2008). Siderophores are not produced by *C. albicans*, but they can be utilized as an iron source even if produced by other microbes (Almeida et al., 2009).

In contrast to other sites in the human body, the gut lumen is probably the only site where microbes encounter high iron levels. Accordingly, as a colonizer of this niche, *C. albicans* is able to adapt not only to iron limitation but also to relatively high iron concentrations. To do so, an intricate system of three transcriptional regulators has evolved that controls iron uptake in *C. albicans* (Blankenship and Mitchell, 2011; Polke et al., 2015). The transcriptional repressor Sfu1 and the virulence regulator Hap43 dampen iron uptake and Sfu1 is required for persistence of *C. albicans* in the gut. In contrast, during blood stream infections, when iron is limited, iron uptake is upregulated by Sef1, a process essential for virulence in the systemic mouse model (Chen et al., 2011). Sfu1 represses Sef1, thereby interconnecting the response to low and high iron and adaptation to distinct niches in the host.

Uptake of iron and copper are very tightly connected. The ferroxidase (Fet) is actually a copper-dependent enzyme, and the iron reductases (Fre) are indeed ferric/cupric reductases that reduce Cu^{2+} to Cu^{1+} through the oxidation of Fe^{2+} to Fe^{3+} , and vice-a-versa (Niemic, 2015). Reduced Cu^{1+} is taken up by Cu transporters (Ctr). Ctr1 and Ctr3 are plasma membrane-localized, Ctr2 is vacuolar – and all three transport toward the cytosol. Interestingly, the number of *CTR* copies varies between fungal species and might affect virulence due to an effect on, for example, hyphal growth (Ding et al., 2014). During infection, pathogens face copper starvation as well as copper intoxication. For example, excess copper has been described as a mode of action against intraphagosomal *Mycobacteria* in macrophages (Rowland and Niederweis, 2012). Therefore, copper export and copper detoxifying metallothioneins are important to maintain copper homeostasis. Metallothioneins are conserved in prokaryotes and eukaryotes. A potential role in virulence was demonstrated in *Cryptococcus neoformans*, a facultative intracellular fungal pathogen, but not yet in *C. albicans*. However, *C. albicans* is known to export excess copper, indicating that fungi are primed to resist potential copper poisoning in vivo (Ding et al., 2014). At the same time, copper is essential for pathogenic survival. Most fungal SODs, crucial to withstand superoxide stress, have copper in their active site. In *C. albicans*, Sod1, Sod4, and Sod6 are copper/zinc-dependent, Sod5 was recently described to be a copper only SOD (Gleason et al., 2014). *C. albicans* extracellular Sod4 and Sod5 were demonstrated to detoxify superoxides produced during interactions with macrophages (Frohner et al., 2009).

Of all metal-containing enzymes, 9% use zinc – so zinc is the second most abundant metal cofactor after magnesium (Waldron et al., 2009). Further, zinc stabilizes zinc-finger domains, a function that is especially important in eukaryotic organisms (Decaria et al., 2010). Several studies have demonstrated the importance of zinc in pathogenic and nonpathogenic fungi. *C. albicans* is very sensitive to zinc starvation. Zinc can actually be the limiting factor if all other nutrients are available (Bedell and Soll, 1979; Soll et al., 1981). Zinc acquisition in fungal pathogens is mediated by a small number of proteins and is conserved in *C. albicans* (Fig. 4): Zinc enters the cytoplasm via the Zrt plasma membrane transporters (Zrt1, Zrt2). From there, zinc can be transported further into the vacuole through ZnT transporters (in *C. albicans*: Zrc1). In return, zinc can be mobilized from the vacuolar pool by Zrt exporters (Zrt3). Interestingly, no cellular zinc exporter has been described in fungi, yet. The homeostasis of zinc is regulated on two levels: the expression of Zrt importers, controlled by Zap1, and zinc import and export from subcellular organelles (Wilson et al., 2012). Vacuolar storage might be especially important during infection, since it allows proliferation even under zinc-restricting conditions (Simm et al., 2007). In addition, *C. albicans* uses a zincophore system – a secreted protein that sequesters zinc from host cells and re-associates with Zrt1 to deliver zinc to the fungal cell: Pra1 (Citiulo et al., 2012). The expression of Pra1 is repressed under acidic conditions, but induced under zinc starvation or at neutral/alkaline pH (Citiulo et al., 2012). Remarkably, Pra1 is not only beneficial for the fungus, it is actually immunogenic and immune-modulatory (Wilson, 2015). Amongst many functions, Pra1 can serve as a ligand to neutrophil integrin receptor $\alpha\text{M}\beta\text{2}$ and enhance neutrophil killing (Soloviev et al., 2007). Probably due to this “side effect,” Pra1 is not conserved in all pathogenic fungi (Wilson, 2015). A role in virulence for zinc acquisition systems has not been directly demonstrated; however, zinc is important for biofilm formation, and involved in tolerance to intrinsic oxidative stress by the cytoplasmic Sod1 (Wu et al., 2009). Sod1 is a copper/zinc SOD. Notably, the cell surface Sods Sod4 and Sod6 that are crucial to survive host-derived ROS, have copper and zinc as their active site (Frohner et al., 2009).

In non-plant eukaryotes, manganese function is restricted to mitochondrial enzymes, including Sod2 and Sod3. The human host restricts access to manganese by releasing calprotectin that is capable of binding manganese and zinc (Kehl-Fie et al., 2011; Sohnle et al., 2000). Furthermore, manganese (and iron) are actively depleted from the macrophage phagosome (Kehl-Fie and Skaar, 2010). Manganese restriction is important during bacterial infections, but its role during fungal pathogenesis requires more investigation (Corbin et al., 2008; Kehl-Fie et al., 2011; Posey and Gherardini, 2000).

Candida albicans Morphology – Does It Determine the Difference Between Commensalism and Infection?

As mentioned throughout the previous parts, the formation of filamentous growth forms during morphogenesis is generally thought to be essential for *C. albicans* virulence. This concept is based on the observation that *C. albicans* mutant strains locked in either the yeast or hyphal form were attenuated in their virulence in murine infection models (Braun et al., 2000, 2001; Lo et al., 1997; Murad et al., 2001). Given that hyphae have the ability to physically penetrate host cell barriers and hypha formation is associated with production of candidalysin (Brand, 2012; Moyes et al., 2016), it appears obvious that hypha formation significantly affects the ability of *C. albicans* to penetrate tissue, damage host cells, and cause disease. However, hypha formation is co-regulated with several virulence-associated factors, leading to rearrangement of the cell wall and thereby affecting the response of immune cells, and is further associated with stress response and metabolism (Dantas Ada et al., 2015; Inglis and Sherlock, 2013; Monge et al., 2006; O'Connor et al., 2010). It is thus difficult to determine to which extend the formation of hyphae per se contributes to virulence (Kumamoto and Vines, 2005). Most likely, both, yeast and hypha, play distinct roles during the different steps of *C. albicans* infections (Gow et al., 2002; Kumamoto and Vines, 2005; Saville et al., 2003).

While invasive growth and host damage are intrinsically linked during infection, commensalism is characterized by a balance between host and fungus that does not cause host damage (Gow and Hube, 2012). Interestingly, genetic analyses revealed that colonization of the gut is associated with significant expression levels of hypha-associated gene expression, such as *EFH1*, *ECE1*, *RBT4*, and *RBT1* in yeast cells (d'Enfert, 2009; Doedt et al., 2004; Rosenbach et al., 2010; White et al., 2007). Thus, transcriptional programs that were previously considered to be morphology-associated based on in vitro observations might be uncoupled from the filamentation program under distinct environmental conditions. Furthermore, *ECE1*, the gene encoding for candidalysin and required for host cell damage, is upregulated in the gut. This raises the question whether growth as yeast in the gut truly reflects a benign, commensal transcriptional program and whether separate commensal and pathogenic transcriptional programs exist. Possibly, the yeast morphology in the gut might be the consequence of complex interactions between host, microbiota, and *C. albicans*. Factors that have so far been only associated with *C. albicans* infections may be required for fungal survival in the gut. Indeed, recent gene network analyses of TFs required for gut colonization and/or fitness during systemic infection revealed several connections between the regulons of TFs important for either commensalism or virulence (Perez and Johnson, 2013).

Further research directed at a better understanding the entire *C. albicans* biology, not only as a pathogen but also as a commensal on different mucosa, is required to decipher what it is exactly that facilitates this fungus to be a successful member of the human microbiota. Hopefully, this will contribute to eventually elucidate the specific factors that predispose patients to disseminated candidiasis.

Historical Aspects

Several studies described the bactericidal activity of normal serum as far back as the 1880s, which was lost when blood was heated to 55°C. Buchner called the bactericidal heat labile factor alexin. Pfeiffer and Issaef showed that whole blood from guinea pigs that survived *Vibrio cholerae* infection could protect naïve animals from developing disease. Subsequently, Jules Bordet showed that the bactericidal activity of heated immune serum was restored by fresh serum that itself lacked intrinsic bactericidal activity. Thus, the bactericidal activity of immune serum required a heat-stable factor ('amboceptor', which now called antibody) as well as a heat labile factor (alexin, which subsequently named 'complement' by Paul Ehrlich). The combination of amboceptor and alexin also caused hemolysis.

Euglobulin and pseudoglobulin fractions in serum were both required for complement activity, leading to the initial nomenclature of C'1 and C'2 (the "prime" was omitted following the WHO nomenclature proposed in 1968). Loss of complement activity following treatment of serum with cobra venom and absorption of this activity by yeast led to the discovery of the third component (C3). In the 1940s, Manfred Mayer and colleagues developed a standardized method of hemolytic titration. Mayer proposed the "one-hit" theory, whereby only one complete sequence of complement proteins was required to lyse an erythrocyte, which permitted titrating the hemolytic activity of sera. The identification of C3 as β 1c-globulin – a major component of serum that was present at concentration of ~1 mg/ml – by Müller-Eberhard and colleagues, paved the way to further characterize complement proteins.

Although not appreciated at the time, the existence of the alternative pathway (*i.e.*, not requiring antibody) was suggested by experiments where cobra venom factor and zymosan consumed complement activity without affecting the classical pathway. Pillemer and his coworkers first characterized the properdin pathway, but his critics ascribed the observations to small amounts of contaminating antibody. Following his untimely suicide in 1957, Pillemer's work was carried on by Irwin Lepow and several other groups, which led to characterization of the alternative pathway by the early 1970s. In Pillemer's memory, alternative pathway proteins were designated with letters of the alphabet, as he had originally proposed.

Evolution of Complement

The complement system developed long before the evolution of adaptive immunity. Acquired immunity appears to have arisen early in vertebrate evolution, between the divergence of cyclostomes (lampreys) and cartilaginous fish (sharks). Genes encoding molecules of the acquired immune system, including immunoglobulin (Ig), T-cell receptor (TCR), major histocompatibility complex (MHC) class I and II, and recombination-activating gene (RAG), have been identified only in sharks and higher vertebrates. The alternative and the lectin pathways are phylogenetically older than the classical pathway. C3, the central molecule of complement, C4 and C5 are all derived phylogenetically from a serum protease inhibitor called α 2-macroglobulin. Only a single C3/C4/C5 gene that is distinct from the α 2-macroglobulin gene was identified in the lamprey, the ascidian and the sea urchin, which suggested that the gene duplication that gave rise to distinct C3, C4 and C5 molecules occurred later in evolution, around the time of the appearance of jawed vertebrates. The classical and terminal complement pathways are believed to have developed around the same time as the adaptive immune system.

Synthesis, Distribution and Catabolism of Complement

The liver is a major site of synthesis of most complement proteins. Several other cell types, such as neutrophils, monocytes, macrophages, adipocytes, microglia, astrocytes, fibroblasts, cervical epithelial cells and endothelial cells also contribute to complement production locally. Complement proteins have higher fractional catabolic rates and are metabolized more rapidly than most serum proteins. Several complement proteins are acute-phase reactants and their synthesis is modulated by cytokines such as IFN- γ , IL-1, and TNF and by endotoxin. Monocytes and macrophages synthesize complement in amounts sufficient to opsonize microbes, therefore upregulation of complement production by proinflammatory signals enhances anti-microbial activity at sites of infection. Locally synthesized complement is important for several physiologic processes, such as the shaping of adaptive immune responses and neural remodeling.

Complement is found at almost every mucosal site and body fluid. Complement concentrations at mucosal sites approach 5%–10% that seen in serum. An increase in complement concentrations at sites such as the cerebrospinal fluid occurs during infections or inflammatory processes because of increased vascular permeability and because of increased local production by inflammatory cells. Complement levels in the female genital tract is profoundly affected by hormonal regulation.

Both preterm and full-term newborns have lower complement function compared to adults. Complement activity correlates inversely with the age of gestation, and approaches adult levels at about 6 months of age.

Activation of the Complement System

Complement activation has traditionally been considered to occur through one of three pathways – the classical, lectin or alternative pathways (Fig. 1). In most instances, complement is activated through more than one pathway simultaneously. As an example, C3b deposited through the classical or lectin pathways often recruits the alternative pathway. For ease of understanding, each pathway is considered separately. Characteristics of each of the components of complement in the fluid phase are listed in Table 1.

The Classical Pathway

The classical pathway is initiated by binding of antibodies to their target antigens, which is followed by specific noncovalent interactions between Fc regions of proximate IgG molecules to form ordered hexamers. These hexamers can engage each of the six globular heads of C1q (a member of the C1 complex that contains C1q, C1r and C1s), thereby converting low-affinity Fc-C1q interactions ($K_d \approx 10^{-4}$ M) to high-avidity interactions. C1r and C1s are arranged as a tetramer (C1s-C1r-C1r-C1s) and form a Ca^{2+} -dependent catalytic subunit. A conformational change in the C1 complex as a result of C1q binding auto-activates C1r, which in turn activates C1s. C1r and C1s are both activated through cleavage of an Arg-Ile bond.

Fig. 1 Schematic representing the activation of the complement cascade. The fragments released into solution are indicated in blue font. The key fluid-phase regulators are indicated in green font. CRP, C-reactive protein; SAP, serum amyloid P component; PTX3, pentraxins 3; C1 inh, C1 inhibitor; α2-M, α2-macroglobulin; C4BP, C4b-binding protein; FHL-1, factor H like protein-1. From Ram, S., Lewis, L.A., Rice, P.A., 2010. Infections of people with complement deficiencies and patients who have undergone splenectomy. Clin. Microbiol. Rev. 23 (4), 740–780.

Table 1 Characteristics of soluble proteins of the complement cascade

Component ^a	Plasma conc. ($\mu\text{g/ml}$)	Mol. mass (kD)	Structure	No. of genetic loci	Chromosomal assignment
<i>Proteins that activate complement</i>					
<i>Classical pathway proteins</i>					
C1q	70	459	18 polypeptide chains; 6A, 6B, 6C; A-B and C-C linked by disulfides	3 (A, B, C)	1p34–1p36.3
C1r	34	173	Comprises a CUB (C1r/C1s, uEGF, bone morphogenetic protein) module, an epidermal growth factor (EGF)-like module, a second CUB module, two complement control protein (CCP) modules and a C-terminal chymotrypsin-like serine protease domain; dimer (A and B chain linked by disulfide bond)	1	12p13
C1s	31	80	Dimer (A and B chain linked by disulfide bond); modular structure s described for C1r	1	12p13
C4	600	206	β - α - γ ; 1 β - α and 2 α - γ disulfide bonds	2 (C4A, C4B)	6p21.3
C2	11–35	100	1 chain	1	6p21.3
<i>Alternative pathway proteins</i>					
Factor B (FB)	200	90	1 chain	1	6p21.3
Factor D (FD; adipsin)	1–2	25	1 chain	1	19p13.3
Properdin	5–10	55	Cyclic polymers in head-to-tail orientation; dimers: trimers:tetramers in 26:54:20 ratio; each monomer comprises 6 thrombospondin-like repeats (TSRs) and has 14 sites of C-mannosylation	1	Xp11.4–p11.23
<i>Lectin pathway</i>					
Mannan-binding lectin (MBL)	1–5	~25 (subunit monomer)	Subunit – trimers of identical polypeptides; subunits organized into larger oligomers (n ~2 for variant (B, C, and D) alleles and 4–6 for wild-type (A) allele)	1	10q11.2–q21
Ficolin-1 (M-ficolin; ficolin/P35-related protein)	0.04–0.1 (monocytes and PMNs main source)	~32 (subunit monomer)	Subunit – trimers of identical polypeptides; subunits organized into larger oligomers	1	9q34
Ficolin-2 (L-ficolin; hucolin; EBP-37; ficolin/P35)	3–4	34 (subunit monomer)	As with Ficolin-1	1	9q34
Ficolin-3 (H-ficolin; Hakata antigen; thermolabile β -2 macroglycoprotein; thermolabile substance)	18	35 (subunit monomer)	As with Ficolin-1	1	Chr 1
Collectin-10 (Collectin Liver 1; CL-L1)	1.9	44 (subunit monomer)	N-terminal segment (19 aa), collagen-like region (72 aa), α -helical coiled-coil neck region (34 aa), carbohydrate-recognition domain (CRD; 125 aa). Each chain forms trimers, which combine to form higher order oligomers		8q23–q24.1
Collectin-11 (Collectin Kidney 1; CL-K1)	0.3	34 (subunit monomer)	Domain structure same as Collectin-10		2p25.3
MASP-1	6	97	Active form consists of heavy and light chains linked by disulfide bond	1	3q27–28
MASP-2	0.02–0.8	83	Active form consists of A and B chains linked by disulfide bond	1	1p36.3–p36.2
MASP-3	2–12.9	105	Activation splits 105 kD disulfide-linked dimer into A (58 kD) and B (42 kD); B chain is serine protease domain	1	3q27–28
MAp19	?	19	Alternatively spliced version of MASP-2 – contains first 2 domains and 4 additional C-terminal aa's; head-to-tail homodimer	1	1p36.3–p36.2
C3					
C3	1000–1500	190	β - α , linked by disulfide bond. Crystal structure shows organization into 13 domains; 8 macroglobulin	1	19p13.3–p13.2

Table 1 Continued

Component	Plasma conc. ($\mu\text{g/ml}$)	Mol. mass (kD)	Structure	No. of genetic loci	Chromosomal assignment
			domains, and 1 CUB, thioester (TED), anaphylatoxin, linker and C345c domain		
<i>Terminal complement components</i>					
C5	75	190	β - α , linked by disulfide bond	1	9q34.1
C6	45	100	1 chain	1	5p13
C7	90	95	1 chain	1	5p13
C8	55–80	151	α - γ dimer linked by disulfide, noncovalently associated with β	3	(α , β)1p32; (γ) 9q34.3
C9	60	71	1 chain	1	5p13
<i>Complement inhibitory proteins</i>					
C1 inhibitor (C1-INH)	150	104	1 chain; highly glycosylated	1	11q11–q13.1
C4b-binding protein (C4BP)	150–300	~550	7 disulfide-linked α -chains (8 SCRs) linked to β -chain (3 SCRs) via disulfide (major isoform; α 7/ β 1); minor isoforms α 7/ β 0 and α 6/ β 1. β -chain associated with protein S of the anti-coagulation system (C4BP-Protein C4BP-Protein S)	2	(α , β) 1q32
Factor H (FH) ^a	500	155	1 chain (20 SCRs)	1	1q32
Factor I (FI)	34	90	1 chain; comprises FI-MAC domain, scavenger receptor cysteine-rich or CD5 domain, two low-density lipoprotein receptor (LDLr) domains and a serine protease domain	1	4q
FHL-1 (Factor H-like protein 1)	25	43	1 chain (7 SCRs; identical to 7 N-terminal SCRs of factor H, plus 4 unique C-terminal aa's)	1	1q32
Vitronectin (Vn; S-protein)	500	75 (65 kD proteolytic fragment also seen)	1 chain	1	17q11
Clusterin (Cn; SP-40,40; apolipoprotein J)	100–300	60 (predicted); 80 (observed)	Heterodimer linked by 5-disulfide bond motif	1	8p21–p12

^aThe FH family of proteins includes five FH-related molecules called FHR1, 2, 3 4 and 5. The function of these proteins remains to be fully elucidated. See text for details.

^bThe terminology proposed in 2014 jointly by the International Complement Society (ICS) and the European Complement Network (ECN) has been used.

Note: Modified from Ram, S., Lewis, L.A., Rice, P.A., 2010. Infections of people with complement deficiencies and patients who have undergone splenectomy. Clin. Microbiol. Rev. 23 (4), 740–780.

Human IgG subclasses differ in their ability to activate complement; in general, the hierarchy is IgG3>IgG1>IgG2, while IgG4 does not activate complement. In contrast to IgG, where cooperation between several molecules is required to activate complement, a single IgM molecule can activate complement. This is because IgM is a polymer (pentameric or hexameric in the presence or absence of the J chain, respectively) and each target-bound IgM can bind a C1 complex. Thus, on a molar basis, IgM is the most potent activator of the classical pathway.

The classical pathway can also be activated when members of the pentraxin family (includes C-reactive protein (CRP), serum amyloid P component (SAP) and pentraxin 3 (PTX3)) bind to surfaces and engage C1q. A novel mechanism of classical pathway activation described in mice is initiated by the binding of certain pneumococcal polysaccharides to Specific Intracellular Adhesion Molecule (ICAM)-Grabbing Nonintegrin R1 (SIGN-R1), a C-type lectin.

Activated C1s cleaves the C4a fragment (77 amino acids) from the N-terminus of the α -chain of C4 to form the metastable C4b molecule. This exposes the internal thioester bond of C4b that reacts rapidly with nucleophilic (*i.e.*, electron-donating groups) groups such as $-\text{OH}$ or $-\text{NH}_2$ on surfaces to form covalent ester or amide bonds, respectively. If the nascent carbonyl group in the thioester moiety fails to interact with a surface, it reacts with water and remain in solution. Two isoforms of C4, called C4A and C4B, dictate the type of bond formed by C4b (note that C4a and C4b represent cleavage products of C4 that should not be confused with C4A and C4B, the isoforms of intact C4). A His residue at position 1106 in the α -chain of C4B imparts the ability to form ester linkages, while Asp at position 1106 results in 'C4A-like' functionality and forms amide bonds. The type of bond formed may have functional consequences. C4B is believed to possess greater hemolytic activity than C4A. On the other hand C4A binds to complement receptor 1 (CR1) more efficiently and may more effectively clear immune complexes from the bloodstream, which may explain the association between C4A deficiency and autoimmune diseases. In addition to the fact that C4 exists as distinct isoforms, the number of copies of the C4A and C4B genes varies across individuals. Deletions or duplications of C4 genes occur frequently and affects plasma levels of C4. The frequency of C4 gene dosages of 2, 3, 4, 5 and 6 in the Caucasian population is 2%, 25.3%, 52%, 17.3% and 3.3%, respectively. As a result, complete C4 deficiency is extremely rare. Conversely, heterozygous C4

deficiency is very common, and occurs in approximately 25% of the general population. Complete deficiency of either C4A or C4B is also relatively common and occurs in about 6% of the population.

The next step in classical pathway activation involves C2 binding to C4b. C2 is cleaved by activated C1s into the C2a fragment, which remains attached noncovalently to C4b, and C2b, which is released into solution. C4bC2a forms the C3 convertase (C3 cleaving enzyme) of the classical pathway. In this manner, a single C1 complex can cleave several substrate molecules and augment complement activation.

The Lectin Pathway

Activation of complement through the lectin pathway also generates C4bC2a. To date, six lectin molecules that can bind to a variety of terminal monosaccharides and initiate complement activation that have been described. These include the collectins (collagen-containing C-type [calcium-dependent] lectins) mannan binding lectin (MBL) and collectins 10 and 11, and ficolin-1, -2 and -3 (also called M-, L- and H-ficolin, respectively). Ficolins contain a fibrinogen-like domain combined with a collagen-like domain, thus are distinct from collectins.

The recognition molecules of the lectin pathway are organized as trimers; each identical polypeptide subunit in a trimer terminates in a calcium-dependent carbohydrate recognition domain. Trimers are organized into higher order oligomers that resemble a bouquet. MBL shares structural and functional homology with C1q. Similar to C1q, MBL is complexed with serine proteases, termed MBL-associated serum proteases (MASPs). Four such molecules – MASP-1, MASP-2, MASP-3, and MBL-associated plasma protein of 19 kD (MAp19) – are the products of two genes arising from a common ancestor shared with C1r and C1s. MASP-1 and MASP-3 are alternatively spliced products of *MASP1*, while MASP-2 and MAp19 are alternatively spliced products of *MASP2*. MASP-2 cleaves C4 and C2 to generate the classical pathway C3 convertase, as described earlier. An individual with a nonsense mutation in *MASP1* (and therefore lacking both MASP-1 and MASP-3) had a non-functional lectin pathway, which supports a role for MASP-1 in complement activation. Reconstitution of this individual's serum with MASP-1 resulted in MASP-2 cleavage and full restoration of lectin pathway activity. Further, MASP-1 and MASP-2 exist as a co-complex with MBL, supporting a model in which MASP-1 trans-activates MASP-2, analogous to C1r and C1s activation.

Plasma MBL levels are influenced by mutations in the first exon of *MBL2* that encodes the signal peptide and the collagen-like region of the molecule. Three mutations associated with MBL deficiency are G→D at position 54, G→E at position 57 and R→C at position 57, which are termed the B, C and D alleles, respectively. These three mutant alleles are collectively referred to as the "O" alleles, while the wild-type protein is designated as the "A" allele. Each of these point mutations (O alleles) interferes with oligomerization of the three single chains that form the mature protein and are associated with low levels of MBL. In addition to the mutations in the coding region of the gene, three polymorphic sites are found in the 5' untranslated promoter region of the *mbL2* gene: H/L, X/Y, and P/Q. The promoter alleles are found in linkage disequilibrium with the exon 1 SNPs (the O alleles), which results in a limited number of haplotypes. Seven haplotypes have been described: HYPA, LYP A, LYQA, LXPA, HYPD, LYPB and LYQC. When the A, or wild-type alleles are in *cis* with promoter -550/-221 haplotypes HY, LY and LX, the MBL concentrations are high, intermediate and low, respectively. Studies where only genotyping has been used to infer MBL levels should be interpreted cautiously because MBL levels may differ by as much as 10-fold across individuals with identical MBL genotypes.

MBL binds to a variety of terminal monosaccharides, including mannose, N-acetyl-mannosamine, N-acetyl-D-glucosamine, fucose, and glucose. Collectin-11 binds preferentially to L-fucose and D-mannose. The ficolins appear to bind preferentially to acetylated sugars such as N-acetyl-D-glucosamine. In addition, Ficolin-1 (M-ficolin) binds to N-Acetyl-D-galactosamine and select sialoglycans, such as those present in the capsule of *Streptococcus agalactiae*. Ligands reported for Ficolin-2 (L-ficolin) include β-(1→3)-D-glucan, N-acetylneuraminic acid, lipoteichoic acid, C-reactive protein, fibrinogen, DNA and certain corticosteroids, while H-ficolin binds to fucose. Collectin-10 binds mannose, fucose and galactose with high affinity, while collectin-11 binds preferentially to L-fucose and D-mannose. These sugars frequently decorate microbial surfaces but rarely appear as the terminal unit of oligosaccharides or glycoconjugates on human cells, which enables 'self-nonsel' discrimination and targets complement activation to foreign surfaces. Renal ischemia in mice enhances local production of collectin-11, which binds to L-fucose expressed on the surface of stressed renal tubule cells and triggers complement-mediated damage. Lectins share several critical features with IgM ('natural antibodies'): both are polyreactive, bind to surface carbohydrates and binding of a single molecule activate complement.

The Alternative Pathway

Similar to the lectin pathway, the alternative pathway does not rely on initiation by antibodies and thus protects the host from pathogens prior to the development of specific immune responses. Alternative pathway activation is characterized by a unique positive feedback loop that permits self-amplification of the pathway. The principal component of this feedback loop is C3b, which may be generated by "tickover" of C3 (which generates a molecule functionally similar to C3b, as discussed below), or by alternative or classical pathway C3 convertases. Given its central role in complement activation, the structure of C3 is discussed next.

C3 – The central component of complement

All complement pathways converge at the level of C3, the most abundant complement component (plasma concentrations range from 1.0 to 1.5 mg/ml). C3 fragments serve a variety of functions: C3b and iC3b deposited on surfaces are opsonins for phagocytes, while the anaphylatoxin C3a modulates inflammation, lipid metabolism (C3a-desArg, which is generated by cleavage of the C-terminal Arg by carboxypeptidase N is also called acylation stimulating protein) and tissue regeneration.

C3 is composed of an α - and a β -chain linked by a disulfide bond (Fig. 2(A)). Similar to C4, the α -chain of C3 also possesses an internal thioester moiety that forms covalent bonds with target surfaces. The crystal structure of C3 revealed that it is organized into 13 domains (Fig. 2(C)). Cleavage of the C3a fragment from the α -chain activates C3, which is accompanied by marked structural

Fig. 2 C3 structure and activation. (A). The C3 molecule represented as its α and β chains and its degradation products. Arrows indicate physiologic cleavage sites. The location of the thioester bond is indicated by the inverted white triangle. Sites of N-linked glycosylation are shown by the 'inverted lollipop' symbol. Locations of disulfide bridges are also shown. Colors of the amino acid stretches of the α and β chains correspond to domain colors in panel C. (B). The internal thioester bond of C3. Asn, asparagine; Cys, cysteine; Glu, glutamic acid; Gly, glycine. R represents a surface target. (C). The domain organization of C3 and its cleavage products. C3 is organized into 13 domains. Upon activation, C3a is released from the amino terminus of the α -chain of C3. The internal thioester bond becomes exposed and accessible to nucleophilic attack and can react with water or available hydroxyl or amine groups on cell surfaces (B). Analogous reactions occur with C4. Together, these reactions involving C3 and C4 are responsible for covalently linking complement deposition to the cell surface. Activation of C3 is accompanied by an ~ 85 Å displacement of the thioester domain and the resulting C3b molecule can form covalent (either ester or amide) bonds with targets (C). Cleavage of C3b to iC3b also results in conformational changes that contribute to ligand specificity. MG, macroglobulin; LNK, linker; ANA, anaphylatoxin; CUB, complement C1r/C1s, Uegf, Bmp1; TED, thioester-containing domain; α' NT, α' amino-terminal segment. Structure of complement component C3 provide insights into the function and evolution of immunity. *Nature* 437, 505–511, Janssen, B.J., Christodoulidou, A., McCarthy, A., et al., 2006. Structure of C3b reveals conformational changes that underlie complement activity. *Nature* 444, 213–216.

rearrangements among its various domains (Fig. 2(C)). The thioester domain that is 'buried' in native C3 moves about ~ 85 Å, becomes exposed and can react with nucleophiles through formation of a highly reactive acyl-imidazole intermediate with a remarkably short calculated half-life of ~ 30 μ s. If this unstable and highly reactive group does not bind to a surface -OH (or under some conditions, a -NH₂ group), it will react with a water molecule and remain in solution (Fig. 2(B)). The high reactivity and short life of the nascent thioester domain restricts C3 deposition to sites proximate to the site of C3 activation, while sparing more distant (and possibly normal) tissue from 'bystander' damage.

Activation of the alternative pathway

The "tickover" model

As discussed above, the internal thioester bond mediates covalent attachment of C3 to surfaces. Although well concealed in the native C3 molecule, the thioester undergoes spontaneous hydrolysis at a low rate of 0.2%–0.4%/h. The generated molecule, called C3(H₂O), has C3b-like properties, but differs from C3b in that it still possesses the C3a fragment. Similar to C3b, C3(H₂O) also can bind to factor B (FB), properdin, C5, can be further cleaved by the combined action of factor H (FH; cofactor) and factor I (FI; enzyme), and can bind to cellular receptors for C3. In the brief period before its degradation by FH and FI, C3(H₂O) can bind to FB to form C3(H₂O)B, which in the presence of FD and Mg²⁺ forms C3(H₂O)Bb (the Ba fragment is released from FB). Akin to C3bBb, C3(H₂O)Bb has C3 convertase activity and generates more metastable C3b molecules capable of forming covalent bonds with surfaces. Each C3(H₂O)Bb produces on average three to five metastable C3b molecules before being inactivated by FH. Surface-bound C3b then recruits FB and FD to generate surface-bound C3 convertase (C3bBb) and set into motion the positive feedback loop of the alternative pathway. The sequence of events that generate C3 convertases through the "tickover" of C3 are illustrated in Fig. 3(A). C3bBb is inherently unstable and dissociates into its components with a $t_{1/2}$ of about 90 s. Binding of properdin – the only known positive regulator of complement – to C3bBb stabilizes the complex and prolong its half-life 5- to 10-fold, thereby amplifying C3 activation. C3(H₂O) may constitute an important source of intracellular C3 and play an important role in the homeostasis and differentiation of T cells, as discussed below.

The properdin-directed model

The properdin-directed model put forth by Hourcade et al. lent support to Pillemer's original proposal of alternative pathway activation. Each properdin subunit is highly positively charged and composed of six complete thrombospondin type 1 repeat (TSR) domains and a truncated N-terminal TSR domain. Each subunit oligomerizes in a head-to-tail manner to form dimers,

Fig. 3 Initiation of alternative pathway activation. (A). The "tickover" model. C3 undergoes slow, spontaneous hydrolysis, where the internal thioester bond (indicated by a star) that is normally tucked away becomes exposed and reacts with a water molecule to form C3(H₂O). Subsequent Mg²⁺-dependent reactions with FB and FD results in formation of fluid-phase C3 convertase, C3(H₂O)Bb, which then activates more native C3 molecules and enables them to bind covalently to surfaces and further activate the alternative pathway. (B). The properdin-directed model. Properdin binding to activator surfaces can recruit fluid-phase C3b or C3(H₂O) and serves as a platform for formation of C3 convertases on the surface.

trimers and tetramers at a ratio of 26:54:20, respectively. Phagocytes, and in particular neutrophils, are the main site of properdin synthesis and storage. Release of properdin from these cells may increase alternative pathway activation locally at sites of inflammation. Properdin multimers may bind to a select cell surface sulfated glycoconjugates and initiate the alternative pathway. Surface-bound properdin can then recruit C3b or C3(H₂O) that then binds FB and act as a platform for further alternative pathway activation (Fig. 3(B)).

Studies using purified properdin should be interpreted cautiously because properdin forms higher order oligomers and aggregates upon freeze-thawing or with prolonged storage, which may result in artefactual binding to surfaces. Increasing evidence suggests that properdin may bind to cell surfaces solely through C3b.

The Terminal Complement Pathway: Assembly of the Membrane Attack Complex

Binding of C3b to classical and alternative pathway C3 convertases generates C5 convertases (C4bC2aC3b and C3bBbC3b) that can cleave C5 and initiate the assembly of membrane attack complex (MAC). C5 bears structural homology with C3 and C4, but lacks a thioester domain. The addition of C3b to C3 convertases lowers the K_m for C5 >1000-fold, from far above the physiological concentration of C5 in plasma to far below it. Therefore, situations that favor complement activation and rapid C3b generation also facilitate the generation of MAC. Cleavage of C5 releases the 11 kDa C5a fragment, an anaphylatoxin with diverse functions (discussed below). Carboxypeptidase N removes the C-terminal Arg residue to yield C5a-desArg, which possesses only 1%–10% of the inflammatory activity of C5a.

Binding of C5b to hydrophobic sites on cell surfaces exposes binding sites for C6 and C7 to form the C5b-7 complex, which has amphiphilic properties and inserts into cell membranes. C8 then binds to the β -chain of C5b, followed by the addition of one or more C9 molecules. C6, C7, C8 and C9 all belong to the MACPF/CDC (MAC-perforin/cholesterol dependent cytolysin) superfamily of proteins. In its fully assembled state, MAC contains one molecule each of C5b, C6, C7 and C8 and up to 18 molecules of C9. Poly-C9 is responsible for the ring-like configuration of MAC. The external aspect of the tubule is hydrophobic and intercalates into membranes, while the hydrophilic inner aspect of the pore permits passage of water and ions. Cryo-electron microscopy analysis of the entire C5b-9 complex revealed a 'split-washer' configuration, as opposed to a symmetric closed-ring conformation seen with perforin and other cholesterol-dependent cytolysins. Disruption of the membrane proton motive force during pore formation and osmotic damage mediated by the channel may both contribute to the cytolytic and bactericidal actions of MAC.

The Intracellular Complement System

Recent studies have shown the presence of intracellular stores of C3 and C5, which are cleaved by intracellular proteases such as cathepsin L to release C3a and C5a, respectively. C3 may be expressed by T cells themselves, or C3(H₂O), the C3b-like hydrolyzed form of C3 may be taken up from the circulation by cells. Activation of intracellular complement plays an important role in the homeostasis, effector response and contraction of T cells. Intracellular C3a-C3aR interactions induce low levels of mammalian target of rapamycin (mTOR) activation to facilitate T cell survival (homeostasis). T cell activation is triggered by signaling through the T cell receptor (TCR), which results in translocation of C3a and C3b to the cell surface, where they engage C3aR and CD46, respectively. Activation of CD46 increases expression of the CD46 isoform with the Cyt-1 intracytoplasmic 'tail'. Cleavage of Cyt-1 by γ -secretase leads to translocation of Cyt-1 to the nucleus which drives the expression of glucose and amino acid transporters, increases nutrient influx and glycolysis and oxidative phosphorylation, resulting in Th1 expansion. Stimulation of CD46 and T cell receptor increases cleavage of intracellular C5 to release the C5a fragment. C5a-C5a receptor 1 (C5aR1) interactions generates reactive oxygen species (ROS), which in turn activates the NLRP3 inflammasome and IL-1 β release. IL-1 β expression is required for optimal production of IFN- γ and Th1 differentiation. Th1 contraction occurs when the CD46 isoform with the Cyt-2 tail predominates, which in conjunction with the IL-2R signaling, produces the Th1-inhibiting cytokine, IL-10.

Inhibition of the Complement System

Tight regulation of the complement cascade is essential to limit complement activation only to sites of tissue injury or infection, thereby minimizing collateral damage to normal host cells. Targeted activation is achieved by the specificity of antibodies and lectins. Once initiated, complement activation is amplified by the alternative pathway positive feedback loop. However, excessive and uncontrolled activation is limited by the short half-lives of the convertases and anaphylatoxins. Several fluid-phase inhibitory proteins act at various levels of complement activation, including C1, C4b, C3b and MAC. The high plasma concentrations of these inhibitory proteins highlight their importance in minimizing unnecessary complement activation. Several membrane-associated complement inhibitors also dampen complement activation on cell surfaces. Absence or dysfunction of complement inhibitors is associated with diseases such as atypical hemolytic uremic syndrome (aHUS), C3 glomerulopathy and age-related macular degeneration, further underscoring their physiological importance.

Fluid-Phase Complement Inhibitors

C1 inhibitor (C1-INH)

C1-INH belongs to the family of protease inhibitors called serpins (*serine protease inhibitors*) that function by a unique “trapping” mechanism, whereby the enzyme cleaves the inhibitor at its reactive center (between Arg 444 and Thr 445 in C1-INH), which is followed by formation of a covalent complex between the enzyme and the inhibitor (*i.e.*, the inhibitor is a “suicide substrate”). C1-INH is one of the most heavily glycosylated serum proteins. C1-INH directly inactivates both C1r and C1s. Binding of C1-INH to C1r also dissociates C1r and C1s from the activated C1 macromolecule, as well as the entire activated C1 complex (C1q-C1r₂-C1s₂) from immobilized human IgG. C1-INH also inhibits the alternative pathway; C1-INH binds to C3b and blocks FB-C3b interactions, thereby preventing the formation of alternative pathway C3 convertase.

Although its name suggests specificity for C1, C1-INH acts on a variety of substrates including the contact system proteases (factor XII, plasma kallikrein), an intrinsic coagulation protease (factor XI) and the fibrinolytic proteases (plasmin, tissue plasminogen activator). C1-INH deficiency results in hereditary angioneurotic edema, characterized by excessive bradykinin production and increased vascular permeability.

Factor I (FI)

FI is a serine protease that inhibits the classical and alternative pathways by cleaving the α' chains of C4b and C3b, respectively, in the presence of cofactors – C4b-binding protein (C4BP) for C4b, factor H (FH) for C3b and membrane cofactor protein (MCP) and complement receptor 1 (CR1) for both C3b and C4b – to their hemolytically inactive forms. Cleavage of C3b yields iC3b, while cleavage of C4b yields C4c and C4d. The primary site of FI synthesis is the liver, but FI also synthesized by fibroblasts, monocytes, keratinocytes, endothelial cells, myoblasts and primary cervical epithelial cells. FI is an acute-phase protein and is upregulated in endothelial cells, hepatocytes and fibroblasts by LPS and IFN- γ . Complete absence of FI is rare and results in uncontrolled complement activation and complement consumption. These individuals are functionally deficient in complement and predisposed to infections, in particular, invasive meningococcal disease. Loss of function mutations in FI lead to alternative pathway overactivity and results in aHUS or C3 glomerulopathy. FI polymorphisms, some of which result in low serum levels of FI, are associated with an increased risk of AMD.

C4b-Binding Protein (C4BP)

C4b-binding protein (C4BP) inhibits the classical pathway by acting as a cofactor in the factor I (FI)-mediated cleavage of C4b to C4c and C4d, and accelerating dissociation of C2a from the classical pathway C3 convertase (C4bC2a), a property called ‘decay-accelerating’ activity. C4BP is composed entirely of short consensus repeat (SCR) domains, also called complement control protein (CCP) domains. Each SCR domain consists of about 60 amino acids, with four invariant cysteine residues and several other conserved amino acids that are folded into a compact unit. Other complement proteins that contain SCR domains include FH, DAF, MCP, CR1, CR2, FB and C2. Interestingly, most SCR-containing complement proteins interact with C3b and/or C4b.

Factor H (FH) and the FH family of proteins

Analogous to inhibition of the classical pathway by C4BP, FH is a cofactor for FI-mediated cleavage of C3b to iC3b and accelerates the decay of C3bBb. FH also blocks binding of FB to C3b to prevent formation of the alternative pathway C3 convertase. FH contains 20 SCR domains organized as a single chain; the first four N-terminal SCRs are necessary and sufficient for complement inhibition. In addition to inhibiting the alternative pathway in the fluid phase, FH also limits alternative pathway activation on host cells. This property stems from the ability of FH to interact simultaneously with C3 fragments deposited on host cells and specific host glycosaminoglycans (including sialic acid in certain configurations) through domains 19 and 20, respectively. The interaction between FH and “self-polyanions” on cells increases the affinity of FH for C3b, and simultaneously decreases FB-C3b interactions, thus preventing C3 convertase formation. Conversely, the FB binding to C3b is favored over FH-C3b interactions on “activator” surfaces. Similar to complete deficiency of FI, loss of FH is associated with complement consumption and predisposition to meningococcal infections, and with renal pathology (dense deposit disease). Mutation in FH that impair recognition of cell surfaces and C3d – most of which reside in domains 19 and 20 – result in aHUS. A homozygous polymorphism in domain 7 (His instead of Tyr at position 402) significantly increases the risk of age-related macular degeneration (AMD). Compared to FH containing Tyr402, FH with His402 shows impaired binding to malondialdehydes that accumulate in ‘drusen’ (the subretinal lesions of dry AMD). Reduced FH (His402) bound to drusen permits more alternative pathway activation and increased uptake of malondialdehyde-modified proteins by macrophages, with resulting inflammation and ocular damage.

An alternatively spliced variant of factor H called factor H-like protein 1 (FHL-1) contains the first seven N-terminal SCRs of FH and therefore possesses cofactor and decay accelerating activities. There are also five FH-related molecules (FHRs 1 through 5) that are the products of separate genes. FH and the related proteins are arranged in tandem within the Regulation of Complement Activation (RCA) gene cluster on human chromosome 1q32. The FHRs also composed entirely of SCR domains that share varying levels of homology with FH, but none of the FHRs have cofactor or decay accelerating activity. FHRs 1, 2 and 5 exist in circulation as homo- or heterodimers. FHRs have been postulated to block binding of FH to microbial surfaces. As an example, CFHR3, competes with FH for binding to meningococci and promotes complement activation. The homology and proximity of the FH family of genes results in gene deletions, duplications and rearrangements. Expression of FH-FHR hybrid proteins result in disordered regulation of the alternative pathway and are associated with renal disorders, such as aHUS, C3 glomerulonephritis, dense deposit disease and retinal damage in age-related macular degeneration.

Vitronectin (Vn)

Vitronectin (Vn; also known as S protein) inhibits the terminal complement complex at various stages. Vn can occupy the metastable membrane-binding site of the nascent C5b-7 complex to form sC5b-7. Although the sC5b-7 complex can take up further C8 and C9 molecules to form sC5b-8 and sC5b-9, respectively, these vitronectin-containing complexes lack hemolytic activity because the number of C9 molecules is limited to three, which is insufficient to form a pore. Vn also blocks pore formation by perforin, a product of cytotoxic T lymphocytes and natural killer (NK) cells. Vn is a multifunctional protein with several distinct ligands and modulates coagulation, fibrinolysis, pericellular proteolysis, vascular remodeling, cell attachment and spreading.

Clusterin (Cn)

Clusterin (Cn; apolipoprotein J; serum protein 40,40 (SP40-40)) is a heterodimer linked by five disulfide bonds. The highest levels of Cn occur in semen, which contains Cn levels 10-fold above the serum concentrations. Although structurally unrelated to Vn, Cn shares functional similarity with Vn and binds to several sites in MAC to prevent C9 polymerization.

Membrane-Associated Complement Inhibitors

Membrane-associated complement inhibitors are critical to prevent damage to host tissue. Diseases associated with their absence or dysfunction highlights their physiological importance – as examples, loss of CD46 function is associated with aHUS and loss of CD55 and C59 causes paroxysmal nocturnal hemoglobinuria (PNH). A schematic representing the five major membrane-associated complement inhibitors discussed below is shown in Fig. 4.

Complement receptor 1 (CR1; CD35)

CR1 is an integral membrane glycoprotein composed of a C-terminal transmembrane region and an extracellular region composed of a linear array of 30 SCR units. The N-terminal 28 SCRs are further organized as four tandem, long homologous repeats (LHRs) of 7 SCR units each. Four allelic variants of CR1 have been described in humans, which express three to six LHRs. CR1*1 (or CR1-A) is the most commonly encountered allotype and occurs in >80% of most populations studied. CR1 copy number on erythrocytes constitutes another polymorphism. CR1 binds C3b, C4b, C1q and MBL. CR1 possesses cofactor activity and can facilitate FI cleavage of C3b to iC3b, and is the only molecule that can facilitate further cleavage of iC3b to C3c and C3d. CR1 also mediates decay acceleration of C3 and C5 convertases of the classical and alternative pathways.

CR1 is found on erythrocytes, neutrophils, monocytes, glomerular podocytes and certain T cells. Human erythrocyte CR1 mediates binding of complement-opsonized immune complexes or microorganisms and forms the basis for the phenomenon of immune adherence. Clustering of CR1 clusters on cell surfaces allows multivalent binding of immune complexes to RBCs. RBC-bound complexes or organisms are removed as they transit the liver or spleen; in the process CR1 is also lost cell from the surface.

Fig. 4 Schematic representation of membrane-bound complement inhibitors. SCR, short consensus repeat; LHR, long homologous repeat; GPI, glycosylphosphatidylinositol; STP, serine threonine proline.

Given its importance in clearing immune complexes, CR1 expression levels on erythrocytes may also modulate the severity of systemic lupus erythematosus (SLE).

SCR1 of CR1 interacts with the *Plasmodium falciparum* protein PfRh4. In addition to facilitating the entry of *P. falciparum* into RBCs, CR1 promotes erythrocyte rosetting that may contribute to the pathogenesis of cerebral malaria. Several epidemiologic studies have attempted to correlate CR1 allotypes and expression levels with the severity of malaria, often with conflicting results.

CD46 (membrane cofactor protein [MCP])

CD46 is a cofactor for FI-mediated cleavage of C3b and C4b to iC3b and C4d, respectively. CD46 expressed on most nucleated cells. Accordingly, human erythrocytes lack CD46. CD46 contains four SCR domains followed by an O-glycosylated serine/threonine/proline-rich (STP) domain, 12 residues of unknown function and an intracytoplasmic tail. Alternative splicing of the STP region (encoded by the B and C exons; the A exon is rarely used) to the B exon and the cytoplasmic tail to either Cyt-1 or Cyt-2 gives rise to four major isoforms of CD46 called C1, C2, BC1 and BC2. N-glycans in SCRs 2 and 4 are required for cofactor activity. The STP region modulates CD46 function. For example, the BC isoform binds C4b more efficiently than the C isoform and better protects cells against the classical pathway.

CD55 (decay accelerating factor [DAF])

CD55 is a single chain glycoprotein that comprises four SCR domains and a heavily glycosylated STP-rich domain that is attached to the cell membrane through a glycosylphosphatidylinositol (GPI) anchor. CD55 accelerates the decay of classical and alternative pathway C3 and C5 convertases and protects host cells against autologous complement-mediated injury. DAF is present on all blood cells and most other cell types. High levels of DAF are seen on cells that line extravascular compartments, such as the cornea, conjunctiva, oral and gastrointestinal mucosa, exocrine glands, renal tubules, ureter and bladder, cervical and uterine mucosa, and pleural, pericardial and synovial membrane.

CD59 (homologous restriction factor 20 [HRF-20]; Membrane attack complex inhibitory factor [MACIF]; Protectin)

CD59 is also GPI-anchored to the cell membrane. CD59 binds to C8 in MAC and prevents incorporation of pore-forming poly-C9. CD59 may also bind to C9 in partially assembled MAC complexes. The term 'homologous restriction factor' is a misnomer because CD59 can protect cells against 'non-host' complement, albeit to varying degrees. Thus, activity may be host-selective rather than host-restricted. Host-selective complement inhibition also applies to other membrane-bound complement inhibitors such as CD46 and CD55. The ability of non-human membrane complement inhibitors to protect against damage by human complement may have implications in xenotransplantation.

Complement receptor of the immunoglobulin superfamily (CRIg)

CRIg, a type 1 transmembrane IgG superfamily member, exists as two alternatively spliced forms: the longer form, huCRIg(L) encodes both V and C₂-type terminal Ig domains, while the short form, huCRIg(S) encodes only an IgV domain. CRIg is expressed by Kupffer cells, CD14⁺ dendritic cells and non-inflammatory resident macrophages in various tissues, but not on infiltrating macrophages during inflammation or on peripheral blood CD14⁺ monocytes, suggesting a role in maintenance of homeostasis rather than in inflammation. CRIg binds to C3b-opsonized particles and in a murine model accelerates the clearance of *Listeria monocytogenes* and *Staphylococcus aureus*. CRIg also binds to the C3b component of alternative pathway C3 and C5 convertases and prevents their interaction with C3 and C5, thereby inhibiting the alternative pathway.

Complement Receptors

Complement receptors may be classified into: (i) receptors that bind to soluble complement fragments (*e.g.*, C3a and C5a) or (ii) receptors for complement components deposited on surfaces (*e.g.*, C1q, C3b, iC3b, C3d and C4b). The characteristics of the membrane-associated complement receptors are summarized in [Table 2](#).

Receptors for C5a and C3a

C5aR (CD88; C5aR1) is expressed on myeloid-derived cells and non-myeloid cells including vascular smooth muscle, endothelium, epithelium and glial cells and binds to C5a with high affinity ($K_d \approx 1$ nM), but with relatively low affinity ($K_d \approx 660$ nM) to C5a-desArg. C5aR1 is a G-protein coupled receptor, which interestingly is 'pre-coupled' to G-proteins even in the absence of its ligand. C5a-C5aR1 interactions lie below the level of detection when C5aR1 is uncoupled from G-proteins. Activation of C5aR1 results in Ca²⁺ fluxes from intra- and extracellular sources, which is followed by binding of β -arrestins 1 and 2 to C5aR1, resulting in internalization of C5aR1 via clathrin-coated pits. Subsequently, several downstream pathways are stimulated, including PI3K- γ kinase, phospholipase C β 2, phospholipase D and Raf-1/B-Raf mediated activation of MEK1.

A second receptor for C5a, called C5a receptor-like protein (C5L2 or C5aR2), is coexpressed with C5aR1. In addition to C5a, C5L2 also binds to C3a and C3a-desArg. Unlike C5aR, C5L2 couples poorly to Gi-like G protein-mediated signaling pathways and is not internalized following ligand binding. The role of C5L2 remains controversial. While some reports suggest that C5L2 functions as a decoy receptor to antagonize C5aR, other studies show that C5L2 is required for optimal C5a signaling in phagocytes and fibroblasts.

Table 2 Complement receptors and membrane bound complement inhibitors

Protein	Characteristics
<i>Membrane bound complement inhibitors</i>	
CR1	Cofactor for factor I cleavage of C3b to iC3b and further to C3d, and C4b to C4d; binds to MBL and C1q; clearance of opsonized pathogens and C3b/C4b associated with immune complexes ("immune adherence")
CD46	Cofactor for factor I cleavage of C3b and C4b. Ligand for Notch family member Jagged1. Roles in T cell differentiation
CD55	Accelerates the decay of C3 convertase assembled on cells.
CD59	Inhibits the assembly of membrane attack complex (C9 polymerization)
CRlg	Ligand for the β -chain of C3b/iC3b; inhibits alternative pathway C3 and C5 convertases by binding to C3b and preventing interaction of the convertases with C3 and C5, respectively; role for pathogen clearance demonstrated in mouse model
<i>Complement ligands</i>	
CR2	Binds primarily to C3d and C3dg; part of the CR2/CD19/CD81 complex that mediates B cell responses to antigens linked to C3 fragments; receptor for Epstein-Barr virus
CR3	Ligand for iC3b; phagocytosis
CR4	Binds for C3d/C3dg; function not known
C1q receptors (cC1qR and gC1qR)	cC1qR (calreticulin) binds to the collagenous region of C1q; gC1qR binds to the globular domain of C1q; cC1qR – phagocytosis of apoptotic cells, chaperone, Ca^{2+} homeostasis; gC1qR – modulation of complement, kallikrein-kinin and coagulation systems.
SIGN-R1	Complement receptor identified as a murine homolog of DC-SIGN; binds select pneumococcal polysaccharides and C1q and can activate the classical pathway in Ab-independent manner
<i>Receptors for anaphylatoxins</i>	
C3aR	Binds C3a/C3a des-Arg; vasodilatation
C5aR	Binds C5a/C5a des-Arg; chemotaxis; modulates inflammation and sepsis, T cell differentiation

Note: Modified from Ram, S., Lewis, L.A., Rice, P.A., 2010. Infections of people with complement deficiencies and patients who have undergone splenectomy. Clin. Microbiol. Rev. 23 (4), 740–780.

Similar to C5aR, C3aR is also a G-protein coupled receptor. C3aR is present on B lymphocytes, guinea pig ileum, vascular endothelium, adipocytes, and mast cells. Unlike C5aR, stimulation of C3aR initiates Ca^{2+} flux only from the extracellular pool and therefore does not activate PI3K- γ . C3aR activation results in activation of protein kinase C by phospholipase C or mitogen activated protein (MAP) kinases. C3a-C3aR interactions induce cytokine expression through ERK and Akt phosphorylation.

A variety of functions have been ascribed to anaphylatoxins and their receptors. They increase chemotaxis and vascular permeability in sepsis. Higher levels of C3a and C5a are often associated with poorer outcomes. C3a and C5a are important in guiding T-cell responses and differentiation. Interactions between Fc γ Rs and C5aR has also been postulated. Treatment of macrophages with C5a upregulates the activating Fc γ RIII (possess an immunoreceptor tyrosine-based activation motif (ITAM)) and downregulates the inhibiting Fc γ RIIb (possesses an immunoreceptor tyrosine-based inhibition motif (ITIM)), thereby reducing the threshold for Fc γ R-mediated stimulation of macrophages. Macrophage activation releases C5, which produces C5a through the activity of proteases, further upregulating activating Fc γ Rs. Engagement of Fc γ RIIb on the other hand, inhibits signaling through C5aR. Immune complexes containing IgG with highly galactosylated Fc N-glycans link Dectin-1 with Fc γ RIIb, which blocks downstream responses mediated by C5aR.

Receptors for C1q

Cellular receptors for C1q include cC1qR (calreticulin (CR); cC1q/CR) that binds to the collagen domain of C1q and gC1qR (also known as hyaluronic acid-binding protein 1, or p33) that recognizes the globular domain of C1q. cC1qR also binds to the collectins surfactant protein A (SP-A) and MBL. cC1qR is expressed by most cell types, except erythrocytes. cC1qR facilitates clearance of C1q-coated apoptotic cells. Calreticulin also located in the storage compartments of the endoplasmic reticulum. Along with calnexin, intracellular calreticulin functions as a molecular chaperone that regulates glycoprotein folding. By virtue of being a high-affinity Ca^{2+} storage protein, calreticulin also regulates Ca^{2+} homeostasis.

gC1qR is part of the receptor complex for high molecular weight kininogen (HK) on endothelial cells and also binds hepatitis C virus core protein. gC1qR modulates the activity of the kallikrein-kinin and coagulation systems. Soluble gC1qR released by endothelial cells acts as an autocrine signal to induce expression of the bradykinin receptor 1. Engagement of gC1qR on CD4⁺ T cells by HIV-1 glycoprotein 41 (gp41) induces expression of Nkp44L, which targets destruction of these CD4⁺ cells by NK cells and contributes to CD4⁺ T cell depletion in HIV infection. Expression of gC1qR and cC1qR are both upregulated in most malignant cells. They appear to have opposing roles in carcinogenesis; cC1qR enhances phagocytosis and increases tumor destruction, while gC1qR promotes tumor growth by enhancing angiogenesis and metastasis.

Complement Receptor 2 (CR2; CD21)

CR2 (or CD21) is a glycosylated transmembrane protein that is composed of a series of 15 or 16 SCRs. C-terminal to the SCRs is a 22–24 amino acid transmembrane domain followed by a 34-amino acid intracellular domain. CR2 is found on mature

B lymphocytes, follicular dendritic cells, thymocytes, a subpopulation of CD4⁺ and CD8⁺ T cells, basophils, keratinocytes, astrocytes and lacrimal and ocular epithelial cells. CR2 is the principal ligand for C3d and Epstein-Barr virus glycoprotein 350/220. CR2 helps couple innate recognition of microbial antigens to B cell activation. Activation of complement results in deposition of C3 fragments on foreign antigens or microbes; the interaction of C3-tagged antigens with CR2 (CD21) results in formation of the CD21/CD19/CD81 complex and activates B cells, as discussed below.

CR3 (Mac-1; CD11b/CD18; $\alpha_M\beta_2$ -integrin)

CR3 is a β_2 -integrin that mediates binding of neutrophils to endothelial cells and is critical for neutrophil recruitment to sites of infection. CR3 mediates phagocytosis of iC3b-coated microbes, enables extravasation of leukocytes from the circulation to sites of injury or infection and facilitates homing of lymphocytes to tissues. The arginine-glycine-aspartic acid sequence (Arg-Gly-Asp, or the 'RGD motif') present in C3 and other CR3 ligands is an important binding motif for CR3. The C-terminal domain of CD11b contains a lectin site that recognizes microbial polysaccharides such as β -glucan, β -oligomannan and GlcNAc. CR3-dependent cytotoxicity requires engagement of the lectin domain; iC3b-coated cells or pathogens that do not engage the lectin binding site on CR3 only adhere to cells but are not phagocytosed. The lectin site of CR3 also promotes formation of cell surface transmembrane signaling complexes between CR3 and membrane glycoproteins that are attached to cells through GPI anchors and therefore cannot signal on their own, such as CD16b (Fc γ RIIB) and CD87 (urokinase plasminogen activator receptor, or uPAR).

CR4 (CD11c/CD18)

CR4 is also an integrin that binds to iC3b. In addition, CR4 binds to fibrinogen, ICAM-1, LPS and denatured peptides. CR4 is expressed on myeloid cells, tissue macrophages, dendritic cells, activated B cells and lymphoid cells.

Functions of Complement

Innate Immunity – Combating Infection

As discussed above, the complement system discriminates between self and 'non-self' structures such as invading pathogens to target them for elimination. The amplification of C3 and C5 convertases is favored over their decay on 'non-self' structures. Complement activation generates C3a and C5a, which promote vascular dilatation, endothelial permeability and neutrophil chemotaxis. Pathogens marked, or opsonized with C3b and iC3b are targeted for removal by phagocytes through the interactions with CR1 and CR3, respectively. Opsonophagocytosis is mediated mostly through iC3b-CR3 interactions in conjunction with engagement of IgG by Fc receptors (Fc γ R). In contrast to gram-negative bacteria can be killed by MAC insertion, the thick cell walls of gram-positive bacteria and fungi render them resistant to killing by MAC and therefore phagocyte recruitment is required to kill these pathogens.

Most gram-negative bacteria isolated from the blood are resistant to killing by complement, whereas most isolates of the same species isolated from mucosal sites tend to be complement-sensitive. These data point to a central role for complement in host defenses. The increased incidence of infections in individuals with complement deficiencies is further evidence for the role of complement in innate immune defenses.

Complement is critical in combating meningococcal infections. The incidence of invasive meningococcal disease in individuals with defects in the alternative (FD and properdin) or terminal complement (C5 through C9) pathways is increased about 1000- to 2000-fold over rates in the general population. Pharmacologic blockade of C5 by the therapeutic monoclonal antibody eculizumab, an approved treatment for paroxysmal nocturnal hemoglobinuria (PNH) and aHUS, is also associated with a high rate of meningococcal disease.

Paradoxically, persons with terminal complement defects and meningococcal infection experience a lower mortality than complement-sufficient individuals. Severity of meningococcal disease correlates directly with the extent of complement activation and endotoxin levels. This is because an intact terminal pathway is necessary for lipopolysaccharide (LPS) release from the surface of gram-negative bacteria, which could explain the milder disease course observed in individuals with terminal complement defects.

Modulation of the Adaptive Immune Response

B Cells and Humoral Immunity

A role for complement in shaping adaptive immune responses was suggested about 45 years ago, when C3b and C3d were shown to bind to B lymphocytes and follicular dendritic cells (FDCs). Covalent binding of C3b to an antigen marks the antigen for uptake by phagocytic cells or retention by FDCs for recognition by cognate B cells. CD21 (CR2) forms a receptor complex with CD19 and CD81 on B cells and plays a central role in enhancing B cell immunity. Coligation of CD21 and B cell receptor with C3 fragments and antigen, respectively, in antigen-C3 complexes lowers the threshold for B cell activation. As an example, hen egg lysozyme (HEL) coupled to two and three copies of C3d were 1000- and 10,000-fold more immunogenic, respectively, than HEL alone. This 'adjuvant-like' role for C3d enhances responses to antigens that have a low affinity for the B cell receptor.

Complement also enhances B cell immunity by localizing antigen to FDCs within lymphoid follicles. High expression of CD21 and CD35 on FDCs facilitate efficient trapping of immune complexes bound to C3 fragments within the lymphoid compartment.

An intact classical pathway, CD21 and CD35 are necessary for efficient uptake of immune complexes by FDCs. Optimum activation of B cells requires an intact classical pathway and ligands for C3 and C4 fragments, evidenced by the observation that mice deficient in C1q, C4, C3, or CD21/CD35 have impaired humoral responses to thymus-dependent and thymus-independent antigens.

Studies using C1q^{-/-}, C4^{-/-} or C3^{-/-}, or CD21/CD35^{-/-} knockout mice have all demonstrated the importance of complement at several stages of B cell differentiation. B cells first express the CD19/CD21/CD81 complex as they migrate from the bone marrow to the periphery. Cross-linking of the BCR at this early stage in their development results in cell death or anergy rather than activation, thus eliminating self-reactive B cells. B1 cells, the main source of natural antibody, are positively selected during early development. Complement plays a role in the selection and maintenance of B1 cells, evidenced by the altered natural antibody repertoire of CD21/CD35^{-/-} mice.

Regulation of T Cells

C3-deficient mice are highly susceptible to primary infection with influenza A virus. C3-knockout mice show delayed viral clearance and increased viral titers in the lung, attributable to reduced priming of T-helper cells and cytotoxic T lymphocytes in lymph nodes draining the lung and the impaired recruitment into the lung of virus-specific CD4⁺ and CD8⁺ effector T cells that produce IFN- γ . Accordingly, T-helper cell-dependent IgG responses are also reduced in C3^{-/-} mice. C3-coated viral particles are taken up by antigen presenting cells (APCs) through receptors such as CR3 (CD11b/CD18) and CR4 (CD11c/CD18) and results in T cell priming. Lack of C3 reduces APC function and limits T cell priming. Independent of APC function, lack of C3 prevents C3a and C5a generation. Engagement of C3aR and C5aR by these anaphylatoxins may contribute to the pulmonary response to influenza virus.

Cross-linking of CD46 (which is also a receptor for the measles virus) with an anti-CD46 antibody or with C3b (a ligand for CD46) inhibits monocyte IL-12 production, which could contribute to the immunosuppression associated with measles infection. Co-engagement of CD3 and CD46 in the presence of IL-2 induces a T-regulatory 1 (Tr1)-specific cytokine phenotype in CD4⁺ T cells, which produce IL-10 and thus inhibit the activation of bystander T cells. CD46 also binds to Jagged1, a member of the Notch family of proteins; loss of CD46-Notch crosstalk stunts T_H1 responses.

Local production and activation of complement and signaling through C3aR and C5aR determines the outcome of T cell responses. Engagement of Toll-like receptors on dendritic cells (DCs) results in secretion of alternative pathway components and upregulates C3aR and C5aR expression. C3a and C5a act on their cognate receptors on DCs to induce secretion of IL-6, IL-12 or IL-23. Stimulation of CD28 on T cells induces expression of C3aR and C5aR; engagement of the latter by C3a and C5a generated by DCs induces IL-12R expression and subsequently, IFN- γ and IL-2 production. Interleukins secreted by DCs then determine whether responses are skewed toward T_H1 or T_H17. In the absence of activation of DCs through pattern recognition receptors, local complement production ceases and the lack of C3aR and C5aR signaling is associated with increased production of TGF- β and induction of suppressive Foxp3⁺ T_{reg} cells. During this process C5L2 is upregulated and sequesters C5a, further limiting C5aR activation.

Complement and Autoimmunity

Complement plays an important role in solubilizing and clearing immune complexes (ICs). Fc-Fc interactions leads to precipitation of ICs. C1q binding to Fc interferes with Fc-Fc interactions and prevents IC precipitation. Subsequent C3b deposition, aided by alternative pathway amplification, disrupts forces within the IC and prevents further lattice formation. Separation of smaller complexes from the lattice results in solubilization of immune complexes. Thus, the classical pathway prevents IC precipitation while C3b deposition facilitates IC solubilization. Complement is about ten times more efficient in preventing IC precipitation than solubilizing them. This function of complement explains the strong association between defects of the classical pathway and lupus.

ICs bearing C3b are targeted for removal by CR1. Erythrocytes express ~1000 CR1 molecules per cell, while neutrophils express ~60,000 CR1 molecules on their surface. Because erythrocytes outnumber neutrophils in circulation by a factor of about 1000, over 95% of the CR1 in the circulation is found on erythrocytes. IC removal from the circulation occurs as erythrocytes traverse the liver and spleen, where tissue macrophages lining the sinusoids of these organs remove both, CR1 and the ICs adherent to it.

Complement also plays an important role in the disposal of apoptotic cells. The surface of apoptotic cells often contains molecules such as phosphatidylserine, annexin 2 and annexin 5 that bind C1q and activate complement. The 'complement-marked' cell is then eliminated through engagement of C1qR and CR3 on macrophages and dendritic cells. The R77H variant allele in CD11b that is associated with impaired phagocytosis is a strong risk factor for SLE, highlighting the importance of CR3 in clearing apoptotic cells. Factors that contribute to limited inflammation associated with apoptosis include binding of complement inhibitors such as FH and C4BP, which reduces complement activation and elimination of apoptotic cells via CR3 on phagocytes.

Metabolism

Metabolic syndrome is associated with increased systemic inflammation and complement activation. Insulin resistance and obesity are associated with increased concentrations of C3. Fat cells are the main source of FD (FD is therefore also called adipsin), and also secrete FB and C3. Local C3 activation generates C3a, which is rapidly converted to C3a-desArg by carboxypeptidase N. C3a-desArg, which is also known as acylation-stimulating protein, promotes triglyceride synthesis in fat cells by increasing the activity of diacylglycerol acyltransferase.

Complement and Cancer

Complement may play a role in immune surveillance against malignant cells by promoting antibody-dependent cellular cytotoxicity and also through lysis by MAC, but on the other hand may promote tumor growth and metastasis. Cancer cells evade complement by expressing high levels of membrane complement inhibitors such as CD46, CD59 and DAF, and can also recruit fluid-phase complement inhibitors such as FH and FHL-1. C3a and C5a induce the secretion of vascular endothelial growth factor (VEGF), which promotes neovascularization. Complement can degrade the extracellular matrix, which may facilitate tumor invasion and migration. C5a also attracts myeloid-derived suppressor cells (MDSCs) to tumors, which generate reactive oxygen and nitrogen species that interfere with the ability of T cells to respond to tumor antigens. Signaling through C5aR increases proliferation of endothelial and colon cancer cell lines. Activation of C3aR guides cell migration that may promote metastasis. Insertion of sublytic amounts of MAC in cell membranes promotes cell proliferation, inhibits apoptosis, and enhances their resistance to complement-mediated lysis.

Tissue Regeneration, Organogenesis and Synaptic Pruning

Accumulating experimental evidence supports a role for complement in tissue growth and regeneration. Locally produced C3 and C5 facilitates limb regeneration in newts. C3 and C5 knockout mice show impaired liver regeneration. Signaling through the canonical Wnt pathway contributes to age-associated decline in tissue repair and regeneration.

The classical pathway prunes and eliminates unwanted synapses in the developing brain. A recent study associated higher levels of C4A expression in the brain with schizophrenia; the mechanism postulated was excessive complement-mediated synaptic pruning during adolescence. Complement activation also contributes to synaptic loss in mouse models of Alzheimer's disease.

C3a-C3aR interactions guide neural crest migration in *Xenopus* embryos. Impaired collectin 11 (CL-K1) and MASP-1 function results in misdirected migration of neural crest cells during development, which may contribute to development of the 3MC syndrome, a term that encompasses four rare autosomal recessive disorders with overlapping clinical features: Mingarelli, Malpuech, Michels and Carnevale syndromes. The 3MC syndrome is characterized by developmental abnormalities including facial dysmorphism, learning disability, and genital, limb and vesicorenal anomalies.

The context and the extent of complement activation may be important in determining the outcome to the host. Controlled complement activation is important in eliminating apoptotic cells, facilitating adaptive immune responses, aiding tissue regeneration and in organogenesis, while unregulated complement activation may contribute to the pathology of acute myocardial infarction, stroke, hyperacute rejection of organ transplants and to tissue injury in conditions such as hepatic, pulmonary and renal fibrosis, Alzheimer's disease, Parkinson's disease and multiple sclerosis.

Glossary

Coupling protein An ATPase responsible for the transport of DNA during conjugation. It is a hallmark of conjugative systems and homologues are widely distributed throughout nature.

ICE (integrating conjugative element) Chromosomally encoded elements, similar to conjugative transposons, capable of excision, conjugation, and reestablishment in a new host via integration. The excision and integration operations are formally similar to those of integrative phages.

Plasmid An extrachromosomal DNA segment, usually circular, which is capable of autonomous replication via a segment of the plasmid called the replicon.

Relaxase The protein responsible for site-specific nicking at the origin of transfer (*oriT*) in the DNA as well as recircularization after transfer. It covalently attaches to the 5' end of the nicked DNA via a tyrosine. It is a key component of the relaxosome.

Transconjugant A general term for a recipient cell that has successfully been converted to donor cell by conjugation.

Transposon A segment of DNA that is replicated as part of a chromosome or plasmid. It encodes a mechanism, called transposition, for moving from one location to another, leaving a copy at both sites.

Type IV secretion system (T4SS) A widely distributed mechanism for the secretion and uptake of protein and nucleic acids via secretion, conjugation, and transformation.

Abbreviations

Cma	Chromosome mobilization ability
Eex	Entry exclusion
fi/Fin	Fertility inhibition
Hfr	High frequency of recombination
HFT	High frequency of transfer
HGT	Horizontal gene transfer
HSL	Homoserine lactone-like
ICEs	Integrating conjugative elements
IHF	Integration host factor
Inc	Incompatibility groups
kb	Kilobases
LPS	Lipopolysaccharide
Mpf	Mating pair formation
Mps	Mating pair stabilization
NLS	Nuclear localization signals
T4SS	Type IV secretion system
Tc	Tetracycline

Defining Statement

Bacterial conjugation is a widespread mechanism for the transfer of DNA between cells in close contact with one another. This entry summarizes past findings and discusses the better-studied systems in Gram-negative and -positive bacteria as well as the phenomena of mobilization and tumorigenesis in plants, which are related processes.

[☆]*Change History:* August 2014. LS Frost added and updated text and Tables.

This article is a reprint of L.S. Frost, Conjugation, Bacterial, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

Introduction

Bacterial conjugation was first described by Lederberg and Tatum in 1946 as a phenomenon involving the exchange of markers between closely related strains of *Escherichia coli*. The agent responsible for this process was later found to be a site on the chromosome called the F ('fertility') factor. This finding was the basis of bacterial genetics in the 1940s and 1950s and was used extensively in mapping the *E. coli* chromosome, making it the preeminent prokaryotic organism at that time. It was also shown that F could excise out of the chromosome and exist as an extrachromosomal element or plasmid. It was capable of self-transfer to other bacteria and could cotransfer the chromosome, a serendipitous function of F, and integrate randomly into its host's DNA. The F sex factor of *E. coli* also imparted sensitivity to bacteriophages that required the F pilus, which is encoded by the F transfer region, as an attachment site during infection. In the 1960s a number of other conjugative plasmids were isolated, many carrying multiple antibiotic resistance markers. These plasmids were termed R ('resistance') factors and were found in many instances to repress pilus expression and conjugation by F, a process termed fertility inhibition (fi^+). The number of conjugative plasmids discovered has grown tremendously in the last few decades and includes self-transmissible plasmids isolated from Gram-negative -positive bacteria, Archaea, as well as mobilizable plasmids. Conjugative transposons or integrating conjugative elements (ICEs), which move between cells using a conjugative mechanism, excise and integrate into the host chromosome via a process reminiscent of lysogenic phages; an example of a conjugative phage has been described for *Staphylococcus aureus*.

In general, the transfer and replication functions of these mobile elements are often physically linked and the type of transfer system is closely aligned with the nature of the replicon that is described by incompatibility groups (Inc). An excellent summary of the properties of many conjugative plasmids is given in Shapiro (1977).

Bacterial conjugation is now realized to be one of the principal conduits for horizontal gene transfer (HGT) among microorganisms. The process is extremely widespread and can occur intra- and intergenerically as well as between kingdoms (bacteria to yeast or to plants). DNA sequence analysis has revealed that conjugation, and in some cases transformation, two of the main conduits for HGT, are effected by a transenvelope protein complex that belongs to the type IV secretion system (T4SS). The effect of this process on evolution has been immense with bacteria rapidly acquiring traits both good (hydrocarbon utilization) and bad (antibiotic resistance, toxins). Once again, bacterial conjugation is at the forefront of microbiology but this time the emphasis is on the process itself rather than its utility as a geneticist's tool. Excellent reviews of the topic are provided in *The Horizontal Gene Pool*, *Bacterial Plasmids and Gene Spread* (C.M. Thomas, ed.) and *Plasmid Biology* (Phillips, G. and Funnell, B., eds.).

Conjugative Process

Unlike other processes like transformation and transduction that contribute to HGT, conjugation can be distinguished by two important criteria. There must be close cell-to-cell contact between the donor and recipient cells and DNA transfer must begin from a specific point on the transferred DNA molecule, be it a plasmid, transposon, or chromosome (Figure 1). This point is encoded

Figure 1 Summary of the mating process for universal (plasmid F) and surface-preferred (plasmid RP4) conjugation systems in Gram-negative bacteria and the pheromone-activated system of *Enterococcus faecalis* (plasmid pCF10). In universal systems, the pilus attaches to a receptor on the recipient cell surface (1) and retracts to form a stable mating pair or aggregate (2). DNA transfer is initiated (3), causing transport of a single strand in the 5' → 3' direction (4). Transfer is associated with synthesis of a replacement DNA strand in the donor cell and a complementary strand in the recipient (5). The process is terminated by disaggregation of the cells, each carrying a copy of the plasmid (6). The transfer systems of conjugative plasmids in Gram-negative bacteria can be repressed (7) or derepressed (constitutive; 8). Cells carrying RP4 and related plasmids express pili constitutively but the pili are not seen attached to the bacteria. Such cells form mating pairs by collision on a solid surface (8). In Gram-positive bacteria, such as the enterococci, the donor senses the presence of pheromone (*) released by the recipient cell, which triggers mating pair formation (Mpf) and DNA transfer (9). Donor cells are shown as oblongs (blue) and recipient (red) cells as ovals. Pili are blue.

within the origin of transfer (*oriT*) called *nic*. The proteins that act on this site are encoded by *tra* (transfer) or *mob* (mobilization) regions although other designations such as *vir* are now common. In general, each conjugative element encodes an array of proteins for mating pair formation (Mpf) while another set of proteins are involved in processing and transferring the DNA (Dtr). The Mpf genes can further be classified into the genes for pilus formation or mating pair stabilization (Mps) in Gram-negative bacteria or aggregate formation in Gram-positive cocci. A system to prevent close contact between equivalent donor cells is called surface exclusion. The gene products that process the DNA in preparation for transfer usually include a protein (relaxase) that cleaves the DNA in a sequence- and strand-specific manner at *nic* and remains covalently bound to the 5' end in all cases that have been examined. This nucleoprotein complex plus other auxiliary proteins bound to the *oriT* region is called the relaxosome whereas the complex formed between the relaxosome and the transport machinery is known as the transferosome. A hallmark of conjugative systems is the coupling protein, within the cytoplasmic membrane, that connects the relaxosome to the transferosome. A process that prevents the transfer of DNA into the recipient cell after Mpf has occurred is called entry exclusion (Exe). Previously, the terms surface exclusion and entry exclusion were used interchangeably; however, as the details of the process have been refined, it is important to make this distinction.

In Gram-negative bacteria, the process of DNA transfer is triggered upon cell contact whereas in *Enterococcus faecalis* and T-DNA transport by *Agrobacterium tumefaciens*, among others, contact between cells induces a complex program of gene expression leading to DNA transport. Whereas the sequences for a number of conjugative elements have been completed and comparisons have revealed information on the evolution of conjugative elements, a study of the conjugative process has only been undertaken in some depth for IncF, IncI, IncP, IncW elements and the Ti plasmid of *A. tumefaciens* and for the pheromone-responsive system found in some plasmids in *Ec. faecalis*, although studies on other systems such as pIP501 are ongoing. Information is now available on the integration and excision processes of conjugative transposons and ICEs as well as the role of the *mob* genes in mobilizable plasmids. In addition, conjugation in *Streptomyces* has been studied in some detail but is quite different than that described and may use a DNA transport mechanism related to the process of DNA partition during septation in *Bacillus subtilis* (see '*Streptomyces*').

Physiological Factors

The level of transfer efficiency varies dramatically among the various systems. For derepressed or constitutively expressed systems such as F (IncFI) or RP4 (IncP α), maximal levels of mating (~100% conversion to plasmid-bearing status) are possible within 30 min. Plasmids undergoing fertility inhibition usually have a 100- to 1000-fold reduction in mating efficiency whereas other plasmids, especially the smaller plasmids of Gram-positive bacteria and conjugative transposons, mate at barely detectable levels even under the best of circumstances. Factors affecting mating efficiency include temperature with very precise optimums usually being the rule. For instance, F and RP4 mate optimally at 37–42 °C, and IncH plasmids and the Ti plasmid at about 20–30 °C. Other factors include oxygen levels, nutrient availability, and growth phase. Silencing by host-encoded factors such as H-NS is an important phenomenon that is thought to provide control of gene expression by newly acquired DNA through HGT, a process now termed 'xenogeneic silencing'. F⁺ cells in late stationary phase are known as F[−] phenocopies because they are able to accept incoming F DNA and are not subject to surface or entry exclusion. Available literature indicates conjugation to be maximal over a short temperature range, in nutrient-rich environments with good aeration for aerobic organisms.

Liquid versus Solid Support

The ability of some conjugative systems to mate equally well in liquid media or on a solid support is one of the hallmarks of conjugation. Whereas all conjugative elements can mate well on a solid support, usually a filter placed on the surface of a prewarmed nutrient agar plate, many transfer systems, including those of the IncF group and the pheromone-responsive plasmids of *Enterococcus*, mate very efficiently in liquid media. This difference can be attributed to the nature of the Mpf process as thick, flexible pili of Gram-negative bacteria are associated with systems that mate well in liquid media whereas rigid pili, not usually seen attached to the cells (e.g., IncP α), require a solid support for efficient mating. The aggregation substance of *Ec. faecalis* allows high levels of transfer in liquid media but other Gram-positive systems and conjugative transposons mate at low levels and absolutely require a solid support. In general, it appears that mating systems requiring a solid support depend on collision between donor and recipient cells whereas systems that mate well on either medium have a mechanism for initiating contact between freely swimming cells (thick, flexible pili, and aggregation substance). The description of media requirements for many Gram-negative plasmid transfer systems is given in Bradley et al. (1980).

Conjugative Elements

Naturally occurring conjugative elements including plasmids, conjugative transposons, or ICEs, which are incorporated into the host chromosome, can lead to chromosome mobilization ability (Cma), resulting in high frequency of recombination (Hfr). Free plasmids can be divided into self-transmissible (Mpf plus Dtr genes) or mobilizable (Dtr or Mob genes) plasmids and can vary in size from a few kilobases (kb) to large plasmids 100–500 kb in size.

Table 1 Selected conjugative/mobilizable plasmids and conjugative transposons.

Mobile element	Size (kb)	Inc group/host/pheromone ^a	Copy number	Mating surface/pilus type ^b	Mating efficiency/host range
<i>Gram-negative bacteria</i>					
F	100	IncFI	1–2	Liquid/flexible (II)	High (derepressed)/narrow
RP4	60	IncP α	4–6	Solid/rigid (II)	High (constitutive)/broad
ColIB-P9	93	IncI1	1–2	Liquid/rigid (II), thin (IV)	Low (repressed)/narrow
pTiC58	~200	<i>Agrobacterium tumefaciens</i> /HSL	1–2	Solid/rigid (II)	Low (repressed)/narrow
<i>vir</i>	25 (T-DNA)	Plant exudates	1–2	Plants/rigid (II)	
<i>Gram-positive bacteria</i>					
pAD1	60	<i>Ec. faecalis</i> /cAD1	1–4	Liquid	High (10^{-2} per donor)/narrow
pIP501	30.2	Inc18/ <i>Streptococcus agalactiae</i>	3–5	Solid	High (10^{-4} per donor)/broad
pIJ101	8.8	<i>Streptomyces</i>	~300	Solid	High/broad (<i>Actinomycetes</i>)
<i>Mobilizable plasmids</i>					
ColE1	6.6	<i>Escherichia coli</i>	~10	Liquid	High (IncF, –P, –I)/narrow
RSF1010	8.9	IncQ	~10	Solid	High (IncP)/broad
pMV158	5.5	<i>Streptococcus</i> B	12–16	Solid	Low (pAM β 1/pIP501)/broad
<i>Conjugative transposons</i>					
Tn916	18.5	<i>Enterococcus faecalis</i>		Solid	Low ($\sim 10^{-8}$ per donor)/broad
CTnDOT	80	<i>Bacteroides</i> /Tc		Solid	Low ($\sim 10^{-5}$ per donor)/narrow
<i>Integrating conjugative elements</i>					
SXT	99.5	<i>Vibrio cholerae</i>		Solid	Low ($\sim 10^{-4}$ or 10^{-5} per donor)/narrow
R391	89	<i>Providencia rettgeri</i>		Liquid	Low ($\sim 10^{-4}$ or 10^{-5} per donor)/narrow

^aIncompatibility groups (Inc) are listed for *E. coli* except pIP501, which uses the Inc group classification for *Streptococcus*. HSL is homoserine lactone. cAD1 is a pheromone specific for pAD1 of *Ec. faecalis*. CTnDOT transfers at 1000-fold higher frequencies in the presence of tetracycline (Tc)

^bPili can be classified as type IV or type II that are assembled by type II (T2SS) or type IV (T4SS) secretion systems, respectively

Plasmids

In general, Gram-negative transfer systems are approximately 20–35 kb and reside on plasmids from 60 to 500 kb whereas mobilizable plasmids are under 15 kb. The transfer or mobilization regions often represent half or more of the coding capability of the plasmid. Table 1 contains a list of selected plasmids and their characteristics including their pilus type and mating medium preference. In nonfilamentous Gram-positive plasmids, the smaller plasmids (<30 kb) usually have a requirement for a solid support during mating and mate at low levels whereas the larger plasmids mate efficiently in liquid media and express genes for aggregate formation (e.g., *Enterococcus*, *Staphylococcus*, *Lactobacillus*, *Bacillus thuringiensis*). *Streptomyces* is able to mate at high frequency and has the added property of Cma. Each large self-transmissible plasmid can supply the needed Mpf functions for a number of mobilizable plasmids. These mobilizable plasmids have been used to construct vectors that either are maintained in the recipient cell or deliver their cargo of DNA but are unable to replicate in the new host (suicide vectors). This has been a boon for the study of genetics of otherwise recalcitrant bacteria.

Chromosome Mobilization

F undergoes integration into the chromosome via four transposable elements (IS2, IS3a and b, and Tn1000), which either mediate cointegrate formation via a transposition event or more frequently undergo homologous recombination between these sequences and similar elements on the chromosome. Once incorporated into the chromosome, the F replicon is suppressed by the chromosomal replication machinery allowing stable maintenance of the Hfr strain. Like F, which was found incorporated into the host chromosome, other examples of naturally occurring Hfr strains have been reported in the literature including ICEs. Hfr strains have also been constructed using homologous gene segments shared by a plasmid and its host for mapping the host's genome. Since the advent of pulsed-field gel electrophoresis for mapping chromosomes and large-scale sequencing facilities, the utility of Hfr strains for mapping purposes is waning. The procedure for using Hfr strains for chromosome mapping requires that the plasmid integrate near a locus with a few genetically defined markers. The direction of transfer of the chromosome and the time of entry of the markers into the recipient cell is a function of the position and orientation of the plasmid's *oriT* in the chromosome

and its distance from each marker. By laboriously measuring the time of entry of each marker (e.g., antibiotic resistance, amino acid biosynthesis), which must be able to recombine into the recipient's chromosome in such a way as to announce its presence, a map of the chromosome can be generated. The process of mobilizing the entire *E. coli* chromosome takes about 90 min and markers that are distal from *F oriT* are transferred much less efficiently than those more proximally located, a process called the 'gradient of transmission'. The last portion of the chromosome to be transferred contains the *F* transfer region; consequently, the recipient cells in an Hfr mating are seldom, if ever, converted to F^+ (Hfr) status.

Another related property of *F* is imprecise excision out of the chromosome with adjoining chromosomal sequences being incorporated into the circular *F* element that are often large enough to encode complete operons. These elements are known as *F'* (*F* prime) factors, and examples include *Flac*, *Fgal*, and *Fhis*.

Conjugative Transposons and ICEs

The first conjugative transposon, Tn916, which expressed *tetM* (tetracycline (Tc)) resistance, was isolated from *Ec. faecalis* (Table 1) in Clewell's laboratory in 1981. This element excises from the chromosome, circularizes into a nonreplicative intermediate, and expresses functions for transfer to a wide range of recipient cell types at low frequency on solid surfaces. The enzymes responsible for excision and integration (Int, Xis) are related to the corresponding enzymes in lambda (λ) phage. The absence of a small repeated sequence flanking the conjugative transposon as well as a nonrandom site selection mechanism for integration suggests that these elements are evolutionarily more related to phages than true transposons. Excision of the element results in staggered ends that form a heteroduplex structure upon circularization. This heteroduplex structure is derived from the flanking sequences in the chromosome ('coupling sequences'). On the basis of mapping and sequencing the site of insertion and determining which end of the heteroduplex is inherited in the recipient, a model involving single-stranded DNA transfer has been proposed. A second important group of conjugative transposons has been found in the anaerobic Gram-negative genus *Bacteroides*. These elements are usually associated with antibiotic resistance (*tetX*, *erm*) and exhibit increased transfer proficiency in the presence of Tc. That IncJ conjugative plasmids could not be isolated from *E. coli* was puzzling. The realization that they were related to the chromosomally located, conjugative, integrative phage-like SXT element in *Vibrio cholerae* explained why they were not true plasmids. These ICEs appear to lack the property of random site selection during integration but instead integrate at *att*-like sites (e.g., *prfC*), similar to lysogenic phages.

Conjugative transposons demonstrate amazing versatility in mobilizing DNA. They can mobilize coresident plasmids directly or form cointegrates with plasmids or the chromosome. They are also able to harbor other mobile elements such as transposons and move them between cells. In the case of *Bacteroides*, the conjugative transposons are able to excise and mobilize small, nonconjugative, nonreplicative segments of DNA found in the chromosome called NBUs (nonreplicating *Bacteroides* units). While conjugative transposons have been identified in many genera of bacteria especially in Gram-positive bacteria, the details of the conjugation process remain obscure although orthologues of T4SS have been identified within the transfer regions, suggesting that Gram-negative and -positive conjugation are related.

Gram-Negative Conjugation

With the possible exception of *Bacteroides*, all Gram-negative transfer systems encode a conjugative pilus (type II), which is essential for Mpf and DNA transport (Figure 1). In thick, flexible pilus mating systems, the pili are attached to the donor cell and pili-mediated contact between donor and recipient cells is easily visualized with an electron microscope. In the case of rigid pilus mating systems, pili are rarely seen attached to cells but are seen as bundles of pili accumulating in the medium.

Considerable homology has been found among all the transfer systems examined to date within the Gram-negative group of organisms as well as detectable homology with systems in Gram-positive bacteria and Archaea. In Gram-negative bacteria, two broad classes can be identified as F-like or P-like Mpf, with I-like Mpf systems being a subclass of P. Relaxase, as well as the protein that energizes DNA transport, the coupling protein, is conserved throughout these systems as are key proteins in the T4SS, as described below. To date, the principal systems studied include IncF (F, R100-1, R1) and IncHI1, which have F-like Mpf genes, and IncP (RP4, R751), Inc11 (Collb-P9, R64), IncN (pCU1, pKM101), IncW (R388), and the Ti plasmids of *A. tumefaciens*, which encode IncP-like Mpf genes.

Pilus

Structure

The conjugative pilus is a thin filament expressed in relatively low numbers (1–3 per cell), has no set length (usually $\sim 1 \mu\text{m}$), and is randomly distributed on the surface of the cell (Figure 2). The diameter of the pilus is approximately 6–11 nm, with most pili being around 9 nm. Pili isolated from cells usually contain a 'knob' at the base that represents unassembled pilin subunits derived from the inner membrane of the cell. They may also have a pointed tip suggesting another protein or unusual configuration of pilin subunits at the tip and can aggregate into large bundles that can be pelleted in an ultracentrifuge. The pilus is usually composed of a single repeating subunit of pilin arranged in a helical array with a hollow lumen clearly visible in negatively stained electron micrographs. F pili, which are the best studied, have a diameter of 9 nm with an inner lumen of 2 nm and a mass per unit length of $3000 \text{ Da } \text{\AA}^{-1}$ (Arutyunov and Frost, 2013).

Figure 2 Transfer apparatuses of Gram-positive and -negative bacteria. The simplest transfer mechanism is exemplified by Tra in *Streptomyces*, which is homologous to the coupling protein of other systems (not shown). (a) The transfer apparatus of the Ti plasmid illustrates the complexity of the P-type Gram-negative transfer systems. The red arrow is the putative path of the DNA during transfer. Note the presence of three ATPases involved in pilus assembly and DNA transfer. Reprinted with permission from AAAS. (b) The F-type Gram-negative system is similar to that for the Ti plasmid except that it lacks homologues of VirB11 (ATPase) and VirB8. It contains proteins for mating pair stabilization (Mps) (TraG, -N, and -U in orange) as well as a cluster of proteins involved in pilus assembly that form an interaction network (shown in green) (based on Harris and Silverman (2004) *Journal of Bacteriology*. 186: 5480–5485). TrbB (yellow) has DsbC-like activity; TraN, -U, and -H are cysteine-rich. TraD, the coupling protein, is not required for pilus assembly. The relaxase, other members of the relaxosome, and inessential proteins are not shown. (c) The transfer apparatus of pIP501 illustrates the comparative simplicity of a system that spans only one membrane. Homologies among the various systems as well as functions are given in Table 2. Reproduced from Abajy et al. (2007), redrawn with permission

The F pilus is expressed as propilin of 121 amino acids (*traA*), which requires TraQ, a putative chaperone, for insertion in the inner membrane where it is stored in a pool of approximately 100 000 subunits. The 51-amino acid leader peptide is cleaved by the host leader peptidase (LepI) and the pilin subunit is acetylated at the N-terminus by TraX. Transposon insertion studies have revealed that mature pilin is oriented within the inner membrane as two α -helical transmembrane segments with the N- and C-termini facing the periplasm. Assembly by the TraL, -E, -K, -B, -V, -C, -W, -U, -F, -H, -G and TrbC proteins results in the subunits oriented within the fiber such that the acetylated N-terminus is buried within the structure and the C-terminus is exposed on the sides. The pilus appears to assemble at its base rather than the tip, based on evidence using the slowly assembled pili expressed by the IncHI1 plasmid R27.

The RP4 pilin subunit is expressed as a 15 kDa prepilin polypeptide (*trbC* in Tra2), which is processed three times to give a 7.5 kDa mature product that is circular with the N- and C-termini covalently linked. The cleavage reactions at the N- and C-termini are completed by LepI of the host as well as the cyclase, TraF, that removes four amino acids at the C-terminus and cyclizes the pilin. The RP4 transfer region is separated into two parts: Tra1 and -2. In addition to *traF* of Tra1, an essential gene, *trbD-L* are required for

pilus assembly with the exception of TrbK, which is involved in Eex. A homologue of F TraX is present in RP4 (TraP) although its substrate and function are unknown. Circular pilins have been identified in the IncHI1 plasmid, R27, and T-pili of the Ti plasmid of *A. tumefaciens*, that uses a host-encoded cyclase, and are suspected to be present in other mating systems that encode a P-like TraF orthologue.

Phage attachment

Conjugative pili act as the primary receptor for a wide range of bacteriophages. These phages can be divided broadly into those that bind to the pilus tip and those that bind to the sides of the pilus. The structure of the phages includes the single-stranded DNA filamentous phages, the small isometric RNA phages, and the complex double-stranded DNA tailed phages that usually attach near the pilus tip. The filamentous phages specific for F-like pili (Ff phages; M13, f1, fd) attach via a defined region of the pIII attachment protein to an unknown receptor at the pilus tip. The RNA phages such as R17 and Q β , which belong to different phage groups, bind to specific residues in F pilin exposed on the pilus sides. For RP4 (IncP α), the filamentous phage Pf3 binds to the sides of the pilus as does the RNA phage PRR1. The tailed phages such as PRD1 and PR4 bind to the pilus tip, although it appears that infection requires binding to a tip exposed at the cell surface rather than at the end of an extended pilus. These phages have a broad host range including cells bearing IncP, -W, -N, and -I plasmids.

Whereas the pilus is required for initial attachment, the transfer region is not necessarily required for phage penetration or growth. The Ff phages are thought to contact the cell surface via the process of pilus retraction where they interact with the TolA protein and penetrate the cell via the TolQRA pathway. The RNA phages R17 and Q β have differing requirements for the F TraD coupling protein, which energizes the transport of nucleic acid through the conjugation pore, suggesting that R17 is imported via the F transfer machinery whereas Q β is taken up via another pathway. RNA phages have the property of phage eclipse, an extracellular event that involves detachment of the phage capsid from the attachment (A) protein-RNA complex, which is then susceptible to exogenous ribonuclease. This process requires that the pilus be extended from a living cell, suggesting that the cell supplies the energy for phage eclipse in some unknown manner. Mutations in F-pilin that block phage eclipse have been identified.

Role in conjugation

The role of the pilus in conjugation has been controversial but it is now generally believed that pilin is part of the conjugative pore. Mutations that affect pilus formation block both Mpf and DNA transfer. Mutations that affect Mps (e.g., F TraN and TraG) allow initial contacts to form between cells via the pilus and also allow the initiation of DNA synthesis in the donor cell but block DNA transport into the recipient cell. While indirect, this is the best evidence that the pilus is involved in the signaling process whereas the Mps genes are involved in forming the conjugation pore. Other experiments in which donor and recipient cells were not allowed to establish cell-to-cell contact suggested that mating was possible through the extended pilus. The pilus has also been implicated in DNA transport in both the F plasmid (mutations in pilin that block transfer) and the Ti plasmid (cross-linking T-DNA to pilin).

Mating Pair Formation

Conjugation involves the establishment of a mating pair via Mpf, which may be augmented by the process of Mps, a feature of F-like systems. The pilus is thought to identify a receptor on the recipient cell surface that triggers retraction of the pilus into the donor cell, although the route of the pilin subunits in this process is unknown. Pilus outgrowth requires energy whereas retraction occurs by default in the absence of assembly. Thus factors that negatively affect cell metabolism (temperature, poisons, and carbon source) promote retraction. Pilus outgrowth and retraction are ongoing processes whereas binding of recipient cells or phage probably trigger retraction.

Early studies identifying mutations in the recipient cell that affected conjugation (Con⁻) revealed that various components of the heptose-containing inner core of the lipopolysaccharide (LPS) were generally important in Mpf whereas OmpA was required for efficient conjugation by the F transfer system. The F-like systems are each affected by different mutations in the *rfa* (now *wra*) locus in the recipient cell whereas the IncH plasmids seem to recognize a generalized negative charge on the recipient cell surface. The requirements for OmpA by F as well as for specific side chains in the LPS appear to be a function of the outer membrane protein F TraN, which is involved in Mps. The idea that the pilus recognizes negatively charged surfaces nonspecifically remains a possibility. A second protein identified in F that is involved in Mps is TraG. Mutations in *traG* fall into two classes: those in the first two-thirds of TraG that affect pilus formation and Mpf and those that only affect Mps.

Recent studies on the F-like *tra* and Ti *vir* gene products have revealed the presence of a complex transenvelope structure, the transferosome, composed of core T4SS proteins and auxiliary proteins involved in pilus retraction and Mps (Figures 2(a) and 2(b); Table 2). The scaffold for the transferosome consists of a TraB (VirB10)-TraK (VirB9)-TraV (VirB7) complex that spans the envelope. VirB10 has been shown to have TonB-like activity that transduces energy from the inner membrane to the outer membrane; TraK/VirB9 are related to secretins of other secretion systems and TraV/VirB7 are lipoproteins in the outer membrane. Other transfer proteins are also required for pilus assembly (Figure 2(b)) with a group of proteins (TraF, -G, -H, -N, -U, -W, TrbB, -C, and -I), which are characteristic of F-like transfer systems, additionally involved in pilus retraction and conjugative pore formation. Some of these proteins have a high cysteine content (TraH, -N, and -U) whereas others are homologous to thioredoxin with one protein (TrbB, a homologue of DsbC) shown to be involved in disulfide bond formation and protein stabilization.

^aBased on Lawley et al., 2003 and Grohmann et al., 2003; Abajy et al., 2007.

^bF-like systems contain a characteristic gene cluster encoding mating pair stabilization (Mps), disulfide bond isomerization, and pilus retraction proteins (TraF, —H, —G, —N, —U, —V, and —W; TrbB, —C, and —I). G^N refers to the N-terminal region of TraG that is required for both pilus assembly and Mps

^cSLT refers to soluble lytic transglycosylase

An interesting variation of Mps for the IncI1 transfer systems (R64, Collb-P9) that express two types of pili has been identified: thin, flexible pili, which are required for Mps, and thick, rigid pili, which are required for DNA transfer. Research on the thin pili of R64 by Komano's group has revealed that they are composed of type IV pilin (similar to the pili found in pathogens such as *Neisseria gonorrhoeae*) of 15 kDa (*pilS*). These pili have a protein at their tip (*pilV*) whose gene undergoes rearrangement via site-specific recombination by the *rci* gene product to form seven possible fusion proteins, each recognizing a specific LPS structure (e.g., *pilVA'*). Whether these pili retract in order to bring the donor and recipient cells together is unknown although retraction is a general feature of type IV pili. Besides these two cases (F and R64 thin pili), little is known about Mps in other Gram-negative systems.

Surface and entry exclusions

Surface or entry exclusion reduces redundant transfer between equivalent donor cells. Such transfer is thought to be deleterious to the donor cell and is exemplified by the phenomenon of lethal zygotosis, which occurs when a high ratio of Hfr donor to recipient cells is used. Multiple matings with a single recipient cell result in its death because of severe membrane and peptidoglycan damage as well as induction of the SOS response resulting from the influx of a large amount of single-stranded DNA. The surface exclusion genes were first identified as the *ilz* locus (immunity to lethal zygotosis) because of their role in protecting recipient cells during matings with a high ratio of Hfr donor to recipient cells.

The mechanism of entry or surface exclusion is unknown although an exclusion mechanism has usually been found associated with the transfer systems studied to date. One exception is the conjugative transposons that transfer at such low frequency that redundant transfer might not be an important factor. Surface exclusion in the F system involves TraT, a lipoprotein found in the outer membrane, which forms a pentameric structure and blocks Mps. Whether it interacts with the pilus or another component of the F transfer system is unknown. The TraS protein of F is an inner membrane protein that blocks the signal that DNA transfer should begin and is thus associated with the property of Eex. TraS interacts with TraG in the inner membrane of another donor cell as demonstrated by Eex specificity experiments using F and R100 plasmids and R391 and SXT ICEs. Thus, TraG appears to contact the inner membrane of the recipient cell, thereby stapling the cells together as part of the Mps process, which is blocked by TraS. TrbK, a lipoprotein found in the inner membrane of RP4-containing cells, is also thought to cause Eex.

DNA Metabolism

Organization of *oriT*

In Gram-negative transfer systems, the origin of transfer (*oriT*) is ~40–500 bp in length and contains intrinsic bends and direct and inverted repeats that bind the proteins involved in DNA transfer. The *nic* site itself, which is a strand- and sequence-specific cleavage site, is cleaved and religated by relaxase. In most cases, relaxase requires auxiliary proteins that direct relaxase to the *nic* site and ensure the specificity of the reaction. The sequence of the *nic* sites identified to date reveal four possible sequences represented by IncF, —P, and —Q and certain Gram-positive plasmids such as pMV158. In addition, there is usually a protein that binds to multiple sites within *oriT* forming a higher-order structure on the DNA, which is essential for the process. This protein also appears to have a function in anchoring the relaxosome to the transport machinery.

Mechanism of DNA transfer

After Mpf, a signal is generated that converts the relaxosome from the cleavage/religation mode to one where unwinding of the DNA is coupled to transport through the conjugation pore in an ATP-dependent manner. The transfer rate is ~750 nucleotides per second with the F plasmid (100 kb) transferred in a little over 2 min.

In IncF plasmids, TraI is the relaxase/helicase enzyme that binds to a site near *nic* and generates an equilibrium between cleavage and religation. This reaction requires supercoiled template DNA and Mg^{2+} as well as the auxiliary proteins F TraY and host integration host factor (IHF) *in vitro*. TraM is known to promote nicking although it is not absolutely required. The signal that triggers the helicase activity of F TraI, which is essential for DNA transfer, is unknown as is the function of TraI* produced by a translational restart in the *traI* mRNA. TraY binds near *nic* whereas TraM binds to multiple sites, in conjunction with IHF, within the nucleoprotein complex. TraM binds TraI as well as the coupling protein, TraD, an inner membrane protein that utilizes ATP via its two NTP-binding motifs. Thus TraM could mediate the initial interaction between TraI and TraD in F, whereas in other systems, relaxase and coupling protein interact directly. This step precedes transport of relaxase, covalently bound to the 5' end of the DNA, into the recipient cell where religation is thought to occur. The transport of relaxase has been demonstrated for several systems other than F and is now thought to be a general feature of conjugation.

In RP4, a similar arrangement of proteins at *oriT* exists except that there is no role for the host protein, IHF. The relaxase protein, also called TraI, cleaves at *nic* and is part of a complex with TraJ whereas TraH stabilizes the TraI–TraJ complex. TraK binds and bends the DNA at *oriT* to form the nucleosome-like structure thought to be needed to initiate DNA replication. The DNA is delivered to the TraG coupling protein, possibly by another ATPase, specific to P-like systems, called TrbB in RP4 and VirB11 in the Ti plasmids, found in the inner membrane that is independent of the T4SS.

In all cases, the 5' phosphate generated by the cleavage reaction remains covalently bound to the relaxase enzyme via a tyrosine residue using a mechanism that is similar to the initiation of rolling circle replication in some phage and plasmid replicons. The DNA is transferred in a 5' → 3' direction with the first genes to enter the recipient cell called the leading region. Transfer seems to be a precise process with termination of transfer after one copy of the plasmid has been delivered to the recipient cell. A sequence in *oriT*, near *nic*, is important for termination by relaxase in a religation reaction. Both strands of the DNA are replicated by the PolIII enzyme using discontinuous synthesis in the recipient and continuous synthesis either from the free 3' end at *nic* or from an RNA primer in the donor. Although synthesis and transport are coupled in conjugation, DNA synthesis does not drive, nor is it required, for DNA transfer.

In RP4 and IncI plasmids, the transport of a primase protein, Pri (*traC* encoded in Tra1), or Sog in RP4 or IncI plasmids, respectively, has been demonstrated to occur simultaneously with the transport of the DNA, with hundreds of copies being transferred. This protein appears to initiate DNA synthesis in the recipient cell via primer formation although it is not essential for conjugation. In F, no primase is transferred and DNA synthesis is thought to begin via a mechanism utilizing *ssi* sites for single-stranded initiation.

Leading region expression

The first genes to enter the recipient cell in the leading region include genes for preventing the SOS response (*psi*) and for plasmid maintenance via poison–antidote systems such as CcdAB and Flm in F, Hok/Sok in R1, and Kil/Kor in RP4. Although homologues of a single-stranded DNA-binding protein, Ssb, are found on many conjugative plasmids, they are not essential for conjugation. Another interesting but inessential gene is *orf169* in F or TrbN in RP4 that is related to transglycosylases such as lysozyme. Perhaps this gene, which is the first to enter the recipient cell during F transfer, has a role in establishing a new transferosome in the recipient cell. Slowly growing bacteria in natural environments might require this transglycosylase to rearrange peptidoglycan in preparation for pilus assembly and DNA transfer. Homologues in Gram-positive conjugation systems are essential for conjugation, suggesting a role in penetrating the thick Gram-positive cell wall during erection of the transport apparatus.

Regulation

The regulation of genes involved in conjugation has been extensively studied in F, RP4, and Ti (see 'Transfer to plants') plasmids and in Gram-positive conjugation but there is little information on other systems. The regulation of F transfer gene expression depends on both host and plasmid-encoded factors whereas the regulation of RP4 appears to be independent of the host. Also, F is unusual in that there is no evidence for coregulation of transfer and replication, a salient feature of other conjugation systems.

In F there are three main transcripts encoding *traM*, *traJ* (the positive regulator of transfer operon expression), and *traY-I* (33 kb) (Frost and Koraimann, 2010). The P_{Y-X} promoter is controlled by a consortium of proteins, including the essential TraJ protein, TraY, the first gene in the operon, and IHF and SfrA (also known as ArcA) encoded by the host. TraY also controls *traM* expression from two promoters that are autoregulated by TraM. The translation of the *traJ* mRNA is controlled by an antisense RNA FinP, which requires the RNA-binding protein FinO for activity (fertility inhibition; see 'Fertility inhibition'). Extracytoplasmic stress, which upregulates the CpxAR regulon, decreases the levels of TraJ by upregulating the HslVU protease/chaperone pair that degrades TraJ. F transfer gene expression is also silenced by H-NS as it enters the stationary phase with TraJ involved in desilencing the transfer region. This silencing has also been described for other plasmids in response to temperature flux and some plasmids such as F-like R100 encode H-NS-like proteins that form heterodimers with host H-NS, thereby inactivating it and desilencing the transfer region. Other factors have been shown to affect F transfer gene expression including LRP and CRP, which sense the nutritional state of the host cell, and Dam methylation of sites within the *traJ* promoter region during conjugation, which monitors the methylation state of the incoming DNA.

In RP4, transfer is tied very closely to replication with the main replication promoter for *TrfA* divergently oriented and overlapping with the first of two promoters for the *Tra2* transfer region, P_{trbA} and P_{trbB} . In this system, the *trfA* promoter is activated first in the transconjugant, promoting plasmid replication. The P_{trbB} promoter, as well as the promoters in *Tra1* that express the genes for *Dtr*, is also activated in order to establish a new transferosome. Eventually, the main global regulators *KorA* and *KorB* repress expression from these promoters and allow transcription from P_{trbA} that maintains the level of *Tra2* proteins in the donor cell. *TrbA* is a global regulator that represses P_{trbB} as well as the three promoters in *Tra1* encoding the genes for *Dtr*. Thus conjugation leads to a burst in transcription that establishes the plasmid in the new donor cell followed by transcription from either the *trfA* or the *trbA* promoters during vegetative growth.

Fertility inhibition

Fertility inhibition (Fin) is a widespread phenomenon among related plasmids that limits the transfer of competing plasmids coresident in a single cell. The Fin systems of F-like plasmids (R factors) repress F and also autoregulate the expression of their own transfer regions. These systems have two components, the antisense RNA *FinP* and the RNA-binding protein, *FinO*, which together prevent translation of the *traJ* mRNA, *TraJ* being the positive regulator of the P_{Y-1} promoter. *FinO* protects *FinP* antisense RNA from degradation by the host ribonuclease, RNase E, allowing *FinP* concentration to rise sufficiently to block *traJ* mRNA translation. Whereas *finP* is plasmid-specific, *finO* is not and can be supplied from a number of F-like plasmids. This is the basis of the fi^+ phenotype noted in the 1960s for various R factors. F lacks *FinO* since *finO* is interrupted by an IS3 element and consequently is constitutively derepressed for transfer.

In F-like plasmids ($FinOP^+$), 0.1–1% of a repressed cell population express pili. If conjugation is initiated, the transconjugant is capable of high frequency of transfer (HFT) for about six generations until fertility inhibition by *FinOP* sets in. This phenomenon, along with surface or entry exclusion, contributes to epidemic spread followed by stable maintenance of a plasmid in a natural population of bacteria.

Other Fin systems are specified by one plasmid and are directed against another. For instance, F encodes *PifC* that blocks RP4 transfer whereas RP4 encodes the *Fiw* system that blocks the transfer of coresident *IncW* plasmids. Each system has a unique mechanism that has made the study of Fin systems more difficult and has tended to downplay the importance of this phenomenon in the control of the dissemination of plasmids in natural populations.

Gram-Positive Conjugation

Conjugative elements in nonfilamentous Gram-positive bacteria can be subdivided into three groups: small plasmids (<30 kb), usually associated with MLS resistance, exhibiting moderate transfer efficiency on solid surfaces over a broad host range (pAM β 1, pIP501); large plasmids (>60 kb) that mate efficiently in liquid media over a narrow host range and undergo clumping or cell aggregate formation (pAD1, pCF10 in *Enterococcus*, pSK41, pGO1 in *S. aureus*); and conjugative transposons.

Studies on Gram-positive plasmids have revealed that their conjugative systems also encode homologues of T4SS proteins especially relaxase, the coupling protein (an ATPase associated with pilus assembly), and a lytic transglycosylase (Ti VirD2, –D4, –B4, –B1, respectively; Figure 2(c), Table 2). Although constructing the T4S apparatus within the Gram-positive cell envelope has different challenges, the basic mechanism of conjugation appears to be conserved throughout the phylogenetic tree.

In the few systems studied in detail, detection of a recipient cell results in expression of an aggregation substance (AS, Agg, or Clu) that covers the surface of the donor cell and results in the formation of mating aggregates that are visible to the naked eye. This ‘fuzz’ is the result of a complex pattern of gene expression that has been studied in detail in only a few instances, mostly in the large plasmids of *E. faecalis*. This group of plasmids responds to pheromones expressed by the recipient cell whereas the signal that triggers mating aggregate formation in other systems is poorly understood. Plasmids in *S. aureus* produce pheromones that trigger transfer by *E. faecalis*, suggesting a mechanism to broaden the host range for the plasmids of this latter organism.

Enterococcus faecalis

The first conjugative plasmid identified in Gram-positive bacteria was pAD1, which carried a hemolysin/bacteriocin determinant responsible for increased virulence and which caused clumping or aggregation 30 min after the addition of plasmid-free cells. Later it was shown that aggregation and subsequent plasmid transfer were induced by pheromones produced by the recipient cell and released into the medium. These pheromones are hydrophobic peptides of 7–8 amino acids with a single hydroxyamino acid derived from the signal sequences of surface lipoproteins. Each recipient cell releases several pheromones with plasmids from a particular incompatibility group recognizing a specific pheromone with specificity residing in the N-terminus of the peptide. Once the plasmid has become established in the transconjugant, expression of the pheromone is repressed by preventing its synthesis in, or release from, the donor cell. As little as picomolar amounts of pheromone added to donor cultures can induce the expression of the transfer genes. Usually the concentration hovers around 1–10 nmol l^{–1} and a slight increase in pheromone levels is sufficient to induce clumping. Pheromones are named after the transfer system that recognizes them; thus, pAD1 recognizes cAD1 and produces iAD1, an inhibitory peptide that blocks accidental induction of transfer.

The pheromone is recognized by a plasmid-encoded protein and is imported into the cell via the host Opp system (oligopeptide permease). In pAD1, it binds to a repressor, *TraA*, inactivating it and allowing transcription of *TraE1*, a positive regulator required for

induction of transfer gene expression. In pCF10, the pheromone cCF10 causes antitermination of transcription of the *prg* genes (pheromone-responsive gene), generating the 530-nucleotide RNA Q_L and the mRNA for aggregation substance and transfer proteins. The Q_L RNA, in conjunction with the pheromone, associates with the ribosome causing preferential translation of the transfer genes. In either case, transcription of the aggregation substance (AS or Asa1 for pAD1, Asc10 for pCF10) ensues, which is deposited asymmetrically on the surface of the cell until the cell surface is covered. This binds to the binding substance (BS, lipoteichoic acid) on the recipient cell to give the mating aggregates so characteristic of conjugation. Interestingly, both AS and BS have been associated with increased virulence in a rabbit endocarditis model with AS having RGD motifs (arginine-glycine-aspartic acid), which are known to promote binding to the integrin family of cell surface proteins.

Once the pCF10 transferosome is established in the transconjugant, a cytoplasmic membrane protein binds pheromone and prevents its release. The inhibitory peptide, iCF10, is synthesized from a shorter version of Q_L called Q_S . A surface exclusion protein, Sea1 or Sec10 (for pAD1 or pCF10, respectively), is also expressed to reduce aggregation between donor cells and provides a second level of control to prevent redundant mating between plasmid-bearing cells.

There also seems to be a close relationship between replication and transfer in these plasmids with the replication protein PrgW embedded within a region that negatively regulates transfer in pCF10. The replication protein also appears to have a requirement for pheromone that is not yet understood. There are two *oriT*s for pAD1: one within the *rep* gene for plasmid replication and a second dominant one near the genes for relaxase (TraX), and the coupling protein (TraW) on the opposite side of the plasmid. The *oriT* of pCF10 is located near *pcfG*, encoding the relaxase, which is interrupted by a functional group II iteron suggesting tight control of the conjugative process.

Streptomyces

The transfer systems found on conjugative plasmids in the large genus *Streptomyces* differ significantly from those of both nonfilamentous, Gram-positive bacteria and Gram-negative systems in that there is only a single essential transfer protein and no evidence for a relaxase or *nic* site has been found. *Streptomyces* are a medically important source of antibiotics and other therapeutic compounds and are thought to be a major reservoir for antibiotic resistance mechanisms that protect these bacteria from the arsenal of antibiotics they produce.

The conjugative plasmids of *Streptomyces* range in size and structure from the circular 9 kb plasmid pIJ101 to the large linear 350 kb plasmid SCP1. The phenomenon of conjugation in this genus was first identified by the ability of certain integrating plasmids to mobilize chromosomes (Cma). One such plasmid SLP1 (17 kb) excises and integrates at the 3' end of an essential tRNA^{Tyr} gene in *Streptomyces lividans* with tRNA genes providing the loci for integration of a number of phage and plasmids.

Streptomycetes are soil microorganisms that undergo a complex differentiation program whereby spores germinate and form substrate mycelia that penetrate into the support surface followed by the erection of aerial hyphae that are multinucleate mycelia. These mycelia eventually septate and form spores. As the cells enter the hyphal stage, they begin to produce an array of secondary metabolites characteristic of the organism and also enter a phase where they are competent for conjugation between mycelia or mycelia and other organisms such as *E. coli*.

The intermycelial transfer of a plasmid requires one essential protein, for example, Tra, in pIJ101, which has homology to the proteins FtsK and SpoIIIE. This protein is located at the asymmetric septum of sporulating *B. subtilis* cells and ensures that a copy of the chromosome enters the forespore. Since no relaxase protein has been found associated with pIJ101, this might be a conjugation system closely related to partitioning mechanisms involving double-stranded DNA.

Once the DNA has been transferred to one compartment of a long mycelium, the plasmid is distributed to all compartments by the *tra* and the *spd* gene products. This process slows the growth rate of the cell and areas on agar plates where plasmids are spread via inter- and intramycelial transfer form 'pocks' of more slowly growing cells, which resemble plaques on a phage titer plate. This phenomenon has proven useful in identifying cells containing conjugative plasmids.

Mobilization

Mobilization is a widespread phenomenon whereby a smaller plasmid encoding its own *nic* site and Dtr genes (*mob*) utilizes the transport machinery of a usually larger plasmid to effect its own transfer. Many plasmids can be mobilized by plasmids from a number of Inc groups. For instance, ColE1 can be mobilized by plasmids from IncF, -P and, -I groups and less effectively and with different requirements by IncW plasmids. The Mob proteins of ColE1 consist of MbeA (relaxase) and MbeB and C that aid in relaxosome formation. MbeD has an Eex function. In the vector pBR322, derived from ColE1, the *mob* genes are deleted and only an *oriT* region for IncP plasmid mobilization remains. While ColE1 requires TraD, the coupling protein, from F for mobilization, the closely related plasmid CloDF13 supplies its own TraD-like protein, a difference that is commonly seen among mobilizable plasmids.

The most remarkable mobilizable plasmid is RSF1010 and its relatives (~8.6 kb in size) from the IncQ group. These plasmids are mobilized very efficiently by plasmids from the IncP group into an extremely broad group of recipients including bacteria, yeast, and plants. This plasmid encodes three Mob proteins, with MobA being the relaxase. Like ColE1, it requires TraG of RP4, a coupling protein, for efficient conjugation. The *oriT* region is a mere 38 bp in size and is homologous to *oriT* regions in plasmids from Gram-positive bacteria, all of which use a rolling circle mechanism during transfer. RSF1010 can be mobilized into plants and between

agrobacteria by the *vir* region (not *tra*; see 'Transfer to plants') and between strains of *Legionella* using the virulence determinants encoded by the *dot* and *icm* loci involved in macrophage killing (see 'Evolutionary relationships').

Small Gram-positive plasmids are also mobilizable by self-transmissible plasmids but less is known about them although recent studies confirm that they encode T4SS homologues and require a transglycosylase (SLT) (Table 2). The utility of conjugative transposons as genetic tools in Gram-positive bacteria has overshadowed interest in these plasmids that tend to be mobilized at low frequencies over long periods. One plasmid that replicates and transfers via the rolling circle mechanism using different origins is pMV158. It encodes a relaxase (MobM) that cleaves at a *nic* sequence unique to a group of mobilizable plasmids found in Gram-positive bacteria representing the fourth class of *nic* sequences.

Transfer to Plants

The phenomenon of DNA transfer from *A. tumefaciens* to plant cells has features of both Gram-negative (pilus expression) and Gram-positive (induction of *tra* gene expression) bacteria and has been dealt with separately (Figure 3). *A. tumefaciens* carrying large conjugative plasmids such as Ti (tumor-inducing) or Ri (root-inducing) greater than 200 kb cause crown gall disease in plants whereby they induce the formation of tumors at the site of infection. The Ti plasmid encodes a sensor-response regulator system, VirA and VirG, which in conjunction with ChvE, a chromosomally encoded periplasmic sugar-binding protein, process signals from wounded plant tissue. The phosphotransfer reaction from VirA to VirG induces gene expression from the *virA*, *-B*, *-D*, *-E*, and *-G* operons on the Ti plasmid. In addition, the *virC*, *-F*, and *-H* operons are induced but these operons express inessential gene products that affect host range or the degree of virulence. The signals generated by the plant include phenolic compounds, simple sugars, and decreased pH or phosphate content among others.

The *virB* region encodes 11 proteins that are homologous to the gene products in the Tra2 region of RP4 and are distantly related to the gene products of F. They encode the gene for prepropilin (VirB2), which is processed to pilin via a mechanism similar to that for RP4 pilin. A potential peptidase, homologous to TraF in RP4, has been identified (VirF) but its role has not been proven. The assembly of the VirB pilus is highly temperature dependent with an optimum of 19 °C, which is also maximal for the transfer process. The pili along with the T4SS transfer apparatus are localized to the pole of the cell, where transfer occurs.

The specific segment of single-stranded DNA that is transferred to the plant nucleus is called the T-DNA and can be characterized by the right (RB) and left (LB) borders, which are direct repeats of 25 bp. The T-DNA of nopaline-producing Ti plasmids is about 23 kb in length and contains genes for plant hormone expression (13 kb), a central region of unknown function, and a third region for opine (nopaline) biosynthesis (~7 kb). The relaxase, VirD2, in conjunction with VirD1 that is similar to RP4 TraJ, cleaves at RB and subsequently LB in a TraI-like manner and remains attached to the 5' end. VirC1, which binds to an 'overdrive' sequence near the RB, and VirC2 of certain Ti plasmids, enhance T-intermediate formation. Unlike other transfer systems, many copies of the T-DNA segment accumulate in the bacterial cytoplasm suggesting replication is important in this system. The accumulation of T-DNA strands has been puzzling but might represent a strategy by the bacterium to ensure infection of the larger, more complex plant cell.

Figure 3 Signaling pathway used to stimulate T-DNA complex transfer to the plant nucleus and Ti conjugative transfer between *Agrobacterium*. Wounded plant tissue releases phenolics (acetosyringone) and sugars (1) that are detected by the two-component VirA and VirG regulatory system (2). This induces expression of the *vir* genes that encode the transfer apparatus at the pole of the cell that transports the T-DNA to the plant nucleus (3). The T-DNA is incorporated into the plant genome and produces the phytohormones auxin (indoleacetic acid) and cytokinin (4) that trigger tumorigenic growth of the plant tissue. The plant also produces opines (5) whose synthesis is encoded on the T-DNA. These unusual amino acids serve as a food source for *Agrobacterium* and also result in the induction of synthesis (6) of the conjugation factor, *N*- β -oxo-octanoyl-homoserine lactone (AAI; 7). AAI allows quorum sensing, which determines cell density with respect to Ti-plasmid-bearing cells resulting in conjugative transfer to other *agrobacteria* (8).

The DNA in the VirD2–T-DNA complex (T-complex) is thought to be coated with the single-stranded DNA-binding protein, VirE2, in preparation for transport through a conjugation pore composed of the VirB proteins (VirB2–VirB11). The VirD4 coupling protein (an ATPase) appears to work in conjunction with VirB11, another ATPase specific to P-like T4SS systems, to transport the T-complex (Figure 2(b)). Recent evidence suggests that VirE2 and VirD2–T-DNA transport are uncoupled and can occur using separate transfer pores. One of the Vir proteins, VirB1, which is inessential, resembles the transglycosylase of F (Orf169) and RP4 (TrbN) whereas a truncated version of VirB1 (VirB1*) is excreted into the rhizosphere and mediates adhesion between the bacterium at the site of transfer and the plant. Once the T-complex has entered the plant cytoplasm, the DNA is transported to the nucleus via nuclear localization signals (NLS) on the VirE2 and VirD2 proteins. The T-DNA is randomly integrated into the plant genome whereupon it begins to elicit signals for plant hormone production resulting in tumor formation. The T-DNA encodes for the synthesis of auxin (indoleacetic acid) and cytokinin (isopentenyl adenosine), plant hormones that elicit uncontrolled growth at the site of infection. The bacteria derive nutrients from the tumor by the devious method of opine (unusual amino acid) production encoded by the T-DNA. Opines can be classified into about nine different types of compounds including octopine, nopaline, and agrocinopine, with up to three different opines being encoded by a particular T-DNA. Thus Ti plasmids are often referred to as octopine- or nopaline-type plasmids, for instance, depending on the opine they specify. The opines are excreted from the plant and taken up by the *A. tumefaciens* bacteria encoding a region on the Ti plasmid involved in opine utilization. The genes for opine catabolism (e.g., *Occ* for octopine catabolism) match the genes for the synthesis of that class of opines on the T-DNA.

An interesting aspect of Ti plasmid biology is the induction of conjugative transfer between agrobacterial cells in response to the presence of opines. The genes for this process (*tra*) are distinct from the genes for T-DNA transfer (*vir*) and encode a transfer region with homology to RP4 as well as the *vir* region itself.

Conjugative transfer by Ti has a narrow host range, limited to the genus of *Agrobacterium*. However, the host range can be extended to *E. coli* if an appropriate replicon is supplied, suggesting that it is plasmid maintenance and not conjugative functions that affect host range.

The process of inducing conjugative transfer in these bacteria is unique and fascinating. Initially, there is a low-level uptake of opines, which activates the regulatory protein *OccR* in octopine-type plasmids and inactivates the repressor protein *AccR* in nopaline-type plasmids such as pTiC58. This leads to increased expression of the *tra* and opine utilization genes by activation of *TraR*. *TraI* (not to be confused with relaxase proteins of F and RP4 plasmids) is a *LuxI* homologue that synthesizes a signaling compound, *N*- β -oxo-octanoyl-homoserine lactone (*Agrobacterium* autoinducer or AAI), belonging to a diverse class of homoserine lactone-like (HSL) compounds involved in quorum sensing or gene activation in response to changes in cell density (Figure 3). *TraR* is a *LuxR*-like regulatory protein that detects increased levels of AAI and induces transfer gene expression to maximal levels. The result is the dissemination of the genes for opine utilization among the agrobacteria in the rhizosphere. Thus the system demonstrates a certain degree of chauvinistic behavior since the original colonizer of the plant cell shares its good fortune with its neighbors who then outcompete other bacteria in the rhizosphere.

Evolutionary Relationships

With the advent of high-throughput sequencing and easily available databases, comparison of gene sequences has become routine. Considering that the mechanism for conjugation varies surprisingly little among the systems described above, the high degree of relatedness of these systems with one another is expected (Table 2). However, the remarkable finding that there is homology between conjugative systems and the transport mechanisms for a number of toxins and virulence determinants has generated increased interest in these systems. There is almost gene-for-gene homology between the transport system for pertussis toxin of *Bordetella pertussis* (*ptl*) and the *virB* region of the Ti plasmid, which is, in turn, homologous to the genes for pilus synthesis in IncN, –P, and –W transfer systems and is distantly related to those of F-like plasmids. More recently, five *vir* homologues (VirB4, –9, –10, –11, and VirD4) have been found in the *cag* pathogenicity island of *Helicobacter pylori* and some of the Dot/Icm proteins involved in the pathogenesis of *Legionella pneumophila*, which can mobilize RSF1010, are homologous to genes in the *Tra2* region of RP4 as well as the *Trb* region of the Inc11 plasmid R64. In fact, many bacteria carry more than one T4SS that are involved in conjugation, transformation, DNA release, and protein translocation. The number of orthologues is astounding and the versatility of T4SS is only now being appreciated.

Conjugation in Natural Environments

While the process of conjugation is thought to be relevant to the adaptation of organisms to environmental conditions such as the acquisition of antibiotic resistance under continuous pressure for selection, there is much to be learned about the process in nature. Conjugation can be demonstrated in a wide number of situations including the gut of animals, biofilms, soil, aquatic environments including wastewater, and on the surface of plants and animals. However, the level of transfer is usually very low. Most experiments have utilized common lab strains and plasmids, which are good model systems for study but might be irrelevant in nature. Considering the diversity of bacterial species, their vast numbers, and the timescale for their evolution, we have only scratched the surface of this phenomenon in the natural environment. However, studies on domesticated lab strains and plasmids have allowed predictions about the conditions that favor transfer. Most conjugative systems require actively growing cells in exponential phase

and have a fairly precise temperature optimum. The majority of systems studied to date mate more efficiently on solid media. Those systems that mate efficiently in liquid media seem to be found in enteric bacteria and might be associated with diseases transmitted via water. More information is required on the natural hosts for conjugative elements and their contribution to the evolution of these elements in an ecological niche. In addition, the most likely route of transmission, which appears to involve many intermediate organisms, is usually impossible to predict or detect because of the complexity of the system and the unknown role of nonculturable organisms in this process. Thus, we can isolate a plasmid from its environment and we can find evidence for its transfer to a new species but we cannot, at this time, follow the plasmid as it makes its way in the world.

Glossary

Auxostat A continuous culture system in which the rate of feeding is determined by controlling a single growth-dependent parameter while all other parameters, including the dilution rate (D) and the specific growth rate (μ), are adapted accordingly.

$\bar{C}_S$ Steady-state concentration of growth-limiting substrate (S) in fermentor (mol l^{-1} or g l^{-1}).

$\bar{C}_X$ Steady-state concentration of biomass in fermentor (g DW l^{-1}).

Chemostat Named from the phrase *chemically static*, the chemostat is a continuous culture system in which the dilution rate (D), and hence the specific growth rate (μ), is set externally and all other growth parameters will adapt accordingly.

Continuous culture An open culture system in which fresh (sterilized) medium is introduced at a steady flow rate (ϕ), from which the culture fluid is continuously removed at the same rate.

Critical dilution rate (D_c) Rate above which cells are washed-out faster than they can grow.

C_s Concentration of growth-limiting substrate (S) in fermentor (mol l^{-1} or g l^{-1}).

C_{Si} Concentration of substrate in medium supply (mol l^{-1} or g l^{-1}).

C_X Concentration of biomass in fermentor (g DW l^{-1} ; DW = dry weight of cells).

Dilution rate (D) Flow rate of incoming medium divided by the volume of the culture in the continuous culture vessel (h^{-1}).

Fermentor Cultivation vessel with appropriate stirring device and control of temperature, aeration, gas supply, pH, pO_2 , and ports for addition and removal of gas and liquids.

Flow rate (ϕ) Rate at which fresh medium is supplied to the fermentor (lh^{-1}).

Maintenance coefficient (q_m) Maintenance energy requirement of the biomass in culture (g or moles substrate (g DW h^{-1})).

Maximum specific growth rate ($\mu_{\max}$) Rate of increase in biomass (h^{-1}) relative to biomass present when all nutrients are present in excess and no growth inhibitors are present.

Monod saturation constant (K_S) Substrate concentration (g^{-1} or mol l^{-1}) at which the specific growth rate is equal to half of the maximum specific growth rate.

Recycling chemostat A chemostat in which a (major part) of the biomass is retained in the fermentor by using a membrane module. The ratio of the volume of culture effluent and the volume of the filtered spent medium determines the recycle ratio and the density of the retained biomass.

Retentostat A chemostat equipped with a membrane module to allow full retention of the biomass, only spent medium is pumped away.

Specific consumption rate (q_s) Substrate (g or moles) consumed per gram biomass per hour, also equal to μ/Y .

Specific growth rate (μ_s) Rate of increase of biomass relative to the biomass already present (h^{-1}), numerically equal to $\ln 2/t_d$. The subscript s refers to the growth-limiting substrate, but is used optionally.

Steady state Condition of a continuous culture in which changes in cell density and physiological state of the cells are no longer detectable.

Turbidostat A continuous culture with a growth-dependent feedback system, in which the dilution rate is controlled by an internal sensor monitoring turbidity.

Y''_{SX} (**yield factor for biomass on substrate**) Quantity of cells produced per substrate consumed (g DW produced per g or moles substrate consumed).

Y_{SX}^{max} True yield factor for biomass on substrate, that is, the experimental yield factor Y''_{SX} if no maintenance exists (g DW produced per g or moles substrate consumed).

[☆]Change History: June 2019, J.G. Kuenen updated the text and references.

This article is an update of J.G. Kuenen, O.J. Johnson, Continuous Cultures (Chemostats), *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 130–147.

Defining Statement

Continuous culture techniques enable the cultivation of microorganisms at submaximal growth rates under highly controlled, nutrient-limited conditions and, if desired, at high cell density, thereby providing researchers with powerful and reproducible tools that have several advantages over batch cultivation. Continuous cultivation is invaluable for (eco)physiological investigations of microorganisms, including functional genomics studies.

Introduction

Continuous culture is a set of techniques used to reproducibly cultivate microorganisms at submaximal growth rates at different growth limitations in such a way that the culture conditions remain virtually constant (in “steady state”) over extended periods of time. In the steady state, the growth of organisms can be studied in great detail under precisely controlled physiochemical states. Such conditions are amenable to a great deal of mathematical modeling that enables powerful quantitative analysis of microbial activities. Continuous culture principles first appeared in the literature near the middle of the 20th century, notably from work performed in the labs of Herbert, Monod, and Novick. Since that time, continuous culture techniques have become common tools in both research and industry. A large diversity of continuous culture applications exists, of which only a modest subset will be mentioned in the present work. Focus will be on a number of classic and a few up-to-date examples of the use of continuous cultivation in various applications. As will be described, the use of continuous culture has enabled studies into several ecological phenomena, including the relationship between growth rate and intracellular metabolic fluxes, the transcriptional responses of microorganisms to various nutrient limitations, the competitive strategies between microorganisms at low nutrient concentrations, as well as the selection and competition between spontaneous or designed mutants for biotechnological applications. As synergistic tools continue becoming more powerful and widely available, the number of uses and the value of the classic continuous culture techniques will likely continue growing at a comparable rate.

Theory of Continuous Culture

General

Microorganisms, inoculated into a suitable growth medium, will grow at a rate that is the maximum possible under the given conditions. During their growth, the environment will continuously change, but as long as the conditions remain favorable, growth will continue until at least one of the essential substrates in the medium becomes limiting. If all other nutrients are present in excess, this is called the growth-limiting substrate. The specific growth rate of a microorganism is dependent on the concentration of the growth-limiting substrate according to the empirical equation of Monod:

$$\mu = \mu_{\max} \frac{C_s}{K_s + C_s} \quad (1)$$

where μ is the specific growth rate, $\mu_{\max}$ the maximum specific growth rate, C_s the concentration of the growth-limiting substrate, and K_s the Monod saturation constant, which is numerically equal to the substrate concentration at which $\mu = \frac{1}{2} \mu_{\max}$. We will use this very simple mathematical model for growth to introduce the mathematics of the operation of the chemostat. Note that the doubling time (t_d) is related to μ as $t_d = \ln 2 / \mu$.

To obtain sizeable population densities, the substrate concentrations employed in a batch culture are much higher than K_s (K_s values are usually in the nmol l^{-1} range), so that growth occurs at the maximum specific growth rate. Most microbial and biochemical research has been carried out on microorganisms grown under these conditions. An experimental drawback of the batch culture is that during growth the medium composition will change, excretion products may accumulate, and cell density will increase. In view of the adaptability of the physiology of the microbes, this means that the results obtained from such cultures will depend on the time of harvest. Another drawback of cultivation in batch is that questions concerning general physiology, such as cellular metabolic pathways, composition, and enzymology at submaximal growth rates under nutrient-limited conditions, cannot be answered.

In contrast, in continuous culture, it is possible to maintain steady-state concentrations of a growth-limiting nutrient in the culture, which permits growth of microorganisms at submaximal rates. In addition, in continuous culture, parameters such as pH, oxygen tension, concentration of excretion products, and population densities can easily be controlled. Several types of continuous culture methods exist (i.e., auxostat, turbidostat, and the chemostat), but by far the most common is the flow-controlled continuous culture, the chemostat, which will be discussed first.

As already mentioned, the chemostat is used for the cultivation of microorganisms at growth-limiting substrate concentrations. In the medium reservoir all the compounds necessary for growth are present in excess, with the exception of the growth-limiting substrate, C_s . Under these conditions, the microorganisms grow at a specific growth rate, μ , which is lower than the maximum specific growth rate, $\mu_{\max}$. The chemostat is an “open” culture system (often a lab-scale growth vessel or fermentor) in which fresh (sterilized) medium from a medium reservoir is introduced at a steady flow rate, ϕ , from which the culture fluid emerges at the same rate, often by a simple overflow system. With a constant volume, V , and an in-flow rate, ϕ , the dilution rate, D , is defined as

$$D = \frac{\phi}{V} \quad (2)$$

where the dilution rate is expressed in h^{-1} .

In the following a simple mathematical treatment of the operation of the chemostat is presented. To this goal the Monod model for growth as shown in Eq. (1) is used since it leads to simple mathematical formulae that can easily be explained and presented graphically. In this treatment it is also assumed that according to Monod a fixed relationship exists between the amount of substrate consumed and the amount of biomass produced over a large range of growth rates:

$$\frac{dC_X}{dt} = -Y_{SX}'' \frac{dC_S}{dt} \quad (3)$$

where dC_X/dt is the change in biomass concentration over time. Y_{SX}'' is the yield factor and is defined as the amount of cell material produced per amount of substrate consumed. However note that Y_{SX}'' is only a constant as long as the substrate consumption for maintenance purposes is not taken into account as will be explained later in this article.

Biomass: If the medium in the fermentor is inoculated, for example with bacteria, the culture will grow at a given rate. At the same time, a quantity of bacteria will be washed out via the overflow, because the culture is continuously fed and diluted with fresh medium from the medium supply. For the culture it thus follows that the accumulation of biomass is equal to growth minus washout or

$$\frac{dC_X}{dt} = \mu C_X - DC_X = (\mu - D)C_X \quad (4)$$

Hence if $\mu > D$, C_X will increase, while if $\mu < D$, C_X will decrease. If $\mu = D$, an equilibrium will exist. While the formula given above accurately describes the general situation, it can easily be shown that, starting from nonsteady-state conditions, a steady state must inevitably be reached, provided that D does not exceed the critical value D_C :

$$D_C = \mu_{\max} \frac{C_{Si}}{(K_S + C_{Si})} \quad (5)$$

where C_{Si} is the concentration of the growth-limiting substrate in the medium supply. If $C_{Si} \gg K_S$, which is usually the case, then $D_C \approx \mu_{\max}$. However, if $C_{Si} \ll K_S$, the culture will be washed-out at $\mu \ll \mu_{\max}$. If $D < D_C$, the establishment of a steady state may be considered as follows. At $\mu > D$, the biomass concentration, C_X , will increase. Owing to the resulting decrease in substrate concentration (C_S), the specific growth rate μ will then decrease. If μ becomes lower than the dilution rate, D , then C_X will decrease because of washout. Consequently, C_S will increase again. Therefore, it can be concluded that the dynamic equilibrium $\mu = D$ is a stable situation. Accordingly, a steady state will be established automatically. It is usually assumed that a steady state has been reached if C_X has not changed during two volume changes and at least five volume changes, in total, have occurred.

Growth-limiting substrate: Substrate enters the culture vessel at a concentration C_{Si} . Consumption of the substrate by the organisms results in a concentration C_S . The net rate of change in the culture vessel is obtained by a balance equation:

$$\frac{dC_S}{dt} = \text{in} - \text{out} - \text{consumption} \quad (6)$$

in which

$$\text{consumption} = \frac{\text{growth}}{\text{yield}} = \frac{\mu C_X}{Y_{SX}''}$$

It follows that

$$\frac{dC_S}{dt} = D(C_{Si} - C_S) - \frac{\mu C_X}{Y_{SX}''} \quad (7)$$

At steady state, dC_X/dt and dC_S/dt are both equal to zero. This, when combined with Eqs. (4) and (7), gives the equilibrium concentrations $\bar{C}_X$ and $\bar{C}_S$.

If

$$\frac{dC_X}{dt} = (\mu - D)C_X = 0$$

then

$$\mu = D \quad (8)$$

Hence

$$D = \mu_{\max} \frac{\bar{C}_S}{(K_S + \bar{C}_S)} \quad (9)$$

or

$$\bar{C}_S = K_S \frac{D}{\mu_{\max} - D} \quad (10)$$

Furthermore

$$D(C_{Si} - \bar{C}_S) = \frac{\mu \bar{C}_X}{Y'_{SX}} \quad (11)$$

Combining Eqs. (8) and (11), it follows that

$$\begin{aligned} \bar{C}_X &= Y'_{SX} (C_{Si} - \bar{C}_S) \\ &= Y'_{SX} \left(C_{Si} - \frac{K_S D}{\mu_{\max} - D} \right) \end{aligned} \quad (12)$$

where K_S , $\mu_{\max}$, and Y'_{SX} are constants for a microorganism under the specified condition of temperature, medium composition, and the nature of the growth-limiting substrate, respectively. For C_{Si} and D a constant value can be chosen. From Eq. (10) it appears that $\bar{C}_S$ solely depends on D . If K_S , $\mu_{\max}$, and Y'_{SX} are known for a given microorganism, the relationship between $\bar{C}_X$ or $\bar{C}_S$ and D can be predicted at a chosen C_{Si} . This is illustrated in Fig. 1.

The amount of cell material produced per unit of time is given by $D\bar{C}_X$ ($\text{g L}^{-1} \text{h}^{-1}$). This term is also known as the productivity. Note that the theoretical lines often do not follow experimental values when the dilution rate is below $\sim 10\%$ of $\mu_{\max}$. This is because at lower μ , the assumption that Y'_{SX} is a constant (i.e., the Monod model for growth) does not hold (see below). Eq. (12) shows that $\bar{C}_X$ depends on D and C_{Si} and is proportional to C_{Si} if $\bar{C}_S \ll C_{Si}$, which is usually the case in the experimental lab situation. At varying C_{Si} , the relationship between D and $\bar{C}_X$ or $\bar{C}_S$ is illustrated in Fig. 2.

Fig. 1 Steady-state relationships in a continuous culture (theoretical). The steady-state values of substrate concentration, bacterial concentration, and doubling time at different dilution rates are calculated from Eqs. (10) and (12), for an organism with the following growth constants: $\mu_{\max} = 0.8 \text{ h}^{-1}$, $Y'_{SX} = 0.5 \text{ g g}^{-1}$, $K_S = 0.15 \text{ g L}^{-1}$, and a substrate concentration in the medium supply of $C_{Si} = 10 \text{ g L}^{-1}$.

Fig. 2 Effect of varying the concentration of substrate in the medium supply (C_{Si}) on the steady-state relationships in a continuous culture (theoretical). The curves are calculated from Eqs. (10) and (12) for an organism with $\mu_{\max} = 0.8 \text{ h}^{-1}$, $Y'_{SX} = 0.5 \text{ g g}^{-1}$, and $K_S = 0.15 \text{ g L}^{-1}$, for three media with different substrate concentrations of 4, 8 and 16 g L^{-1} .

It is important to note that $\bar{C}_S$ is independent of C_{Si} . At dilution rates well below D_C , relatively high cell concentrations can be obtained at very low, growth-limiting concentrations of the substrate. Hence, high biomass samples of cells that are growing at a submaximal rate and maintained in an active, controlled physiological state, are available for (eco)physiological studies. This is one of the great assets of chemostat cultivation.

In practice, the parameters of a culture such as $\mu_{\max}$, Y''_{SX} , and K_S can be determined in various ways. In the chemostat, $\mu_{\max}$ can usually be determined more reliably than in a batch culture for the following three reasons: (1) prior to the determination of $\mu_{\max}$ the culture can be grown at a rate close to $\mu_{\max}$, ensuring that all cells are optimally adapted to growth at their near-maximum rate; (2) lag phases will not interfere with the measurement; and (3) possible influences of changing the substrate and the product concentrations are minimized. For the actual measurement, the dilution rate is increased (in one step) from a value slightly below $\mu_{\max}$ to a value of 20–50% above the critical dilution rate. This results at once in alleviation of the substrate limitation and in gradual washout of the culture. The rate at which this washout proceeds can be expressed as given in Eq. (4), which after integration gives

$$\ln C_X = (\mu - D)t + \ln C_{X0} \quad (13)$$

where C_{X0} represents the cell density at the start of the washout period. Because the substrate is no longer limiting, the culture grows at $\mu_{\max}$ and a plot of $\ln C_X$ versus t yields a line with a slope of $(\mu - D)$. Because D is fixed at a known value, $\mu_{\max}$ can be determined.

K_S can be obtained from continuous culture experiments by selecting D so large that $\bar{C}_S$ can be measured. Usually $\bar{C}_S$ can only be measured over a small range of dilution rates, and hence the data may give inaccurate results. It is essential to minimize residual substrate consumption during the sampling. This can be done (1) by very rapid sampling in a tube with precooled stainless-steel beads, followed by immediate filtering and (2) by decreasing the C_{Si} so that the steady-state biomass concentration, C_X , and hence the rate of consumption, $\mu C_X/Y''_{SX}$, are lowered. A common way to obtain K_S is to perform a nonlinear fit (with least-squares regression), of the measured $\bar{C}_S$ values in the Monod equation ($\mu = D$) with a proper computer-fitting program. The most accurate method is to use the formula for the specific consumption rate (q_s), discussed below (Eq. (16)). An outdated method for the graphical determination of K_S is mentioned here because it is very commonly used to linearize Eq. (9), which can be rewritten to produce the so-called “Lineweaver–Burk plot”:

$$\frac{1}{D} = \frac{K_S}{\mu_{\max} \bar{C}_S} + \frac{1}{\mu_{\max}} \quad (14)$$

At varying D values, a graphical plot of the reciprocal of $\bar{C}_S$ measured versus the reciprocal of D gives a straight line with an intercept with the y -axis equal to $1/\mu_{\max}$ and an intercept with the x -axis equal to $-1/K_S$. The slope of the line is $K_S/\mu_{\max}$. Practical values of K_S can lie in a range between 10^{-8} and 10^{-3} mol l $^{-1}$, but are usually between 10^{-7} and 10^{-3} mol l $^{-1}$. However this method gives inaccurate results because those points obtained at the low end of the substrate concentration range (which usually are the most inaccurate) have the greatest effect on the position of the line in such a plot. This graphical method has been replaced by the direct linear plot.

The yield factor, Y''_{SX} , can be obtained from batch experiments using a series of cultures with increasing C_{Si} and further by a graphical plot of C_{Si} versus $\bar{C}_X$. However, this method often neither gives data as reproducible nor dependable as that observed from the chemostat. In continuous cultures, Y''_{SX} can be calculated from Eq. (12), according to the simple Monod model for growth, but now we must refine the mathematical treatment of the operation of the chemostat, because in practice it is observed that at low growth rate the yield is strongly influenced by the fact that an organism requires maintenance energy for a number of purposes. The resulting deviation is illustrated in Fig. 3.

Fig. 3 Steady-state biomass concentration $\bar{C}_X$ as a function of the dilution rate D in a chemostat when there is a maintenance requirement for the growth-limiting substrate: $Y''_{SX}^{\max} = 0.5$ g g $^{-1}$, $C_{Si} = 10$ g l $^{-1}$, $q_s^{\max} = 1.6$ g g $^{-1}$ h $^{-1}$, $q_m = 0.08$ g g $^{-1}$ h $^{-1}$, and $K_S = 0.15$ g l $^{-1}$.

In other words, in Eq. (12), Y''_{SX} will not always be a constant. The percentage of the total consumed substrate used for maintenance will increase as μ decreases and, thus, Y''_{SX} will decrease as μ decreases. Marr, and later Pirt, have given an explanation based on the assumption that for its maintenance a cell requires a certain amount of energy per unit of time, independent of the specific growth rate. This means that the total consumption of substrate is equal to the consumption of substrate for maintenance plus consumption of substrate for growth:

$$\frac{\mu C_X}{Y''_{SX}} = q_m \cdot C_X + \frac{\mu C_X}{Y_{SX}^{\max}} \quad (15)$$

If we divide by C_X , we obtain the specific consumption rate of the microorganism, q_s :

$$q_s = \frac{\mu}{Y_{SX}} = q_m + \frac{\mu}{Y_{SX}^{\max}} \quad (16)$$

where q_m is the specific maintenance energy requirement expressed as amount (moles or grams) of substrate consumed per unit of biomass per unit of time. Note that in the literature we often see the symbol m_s instead of q_m . $Y_{SX}^{\max}$ is the maximum yield (also known as the true yield), that is, the growth yield if no maintenance energy is required. The experimentally obtained $Y_{SX}^{\max}$ value should not be confused with the "theoretical" maximum yield that can be calculated from metabolic pathways, which is at least twice as high as the $Y_{SX}^{\max}$.

Maintenance energy is necessary, in the first place, to maintain the proton motive force (PMF). This is a proton gradient across the cell membrane that is essential for various metabolic functions (e.g., maintaining ion gradients across the cell membrane). Furthermore, energy is used in the "turnover" of proteins and mRNA, for repair and motility, among other things. The existence of a maintenance energy requirement can be deduced from the fact that all microorganisms at rest (i.e., not growing) retain a certain respiratory level.

In the older literature, a graphical plot of $1/Y''_{SX}$ versus $1/D$ is used to derive the value of q_m (slope) and $1/Y_{SX}$ (intercept with the y-axis). However, in this type of reciprocal plot the same drawback is observed as pointed out above for the K_S determination. In this case, a plot of q_s against D gives much more dependable results. An example is shown in Fig. 4 (lower line), where the specific rate of oxygen consumption of a carbon- and energy-limited culture is plotted against D . The value of q_s can easily be calculated by monitoring the oxygen content of in- and out-flowing gas and by measuring the biomass concentration in the steady state. The specific maintenance coefficient in this case is expressed as $q_m(O_2)$, that is, the specific oxygen consumption for glucose respiration at $D = 0$. If the specific glucose consumption rate, $q_{s(\text{glucose})}$, instead of q_{O_2} , would be plotted as a function of D , the experimental yield is measured and the $q_{s(\text{glucose})}$ is calculated from the equation $q_s = \mu/Y''_{SX}$.

Although q_m can directly be read from the graph at $D = 0$, the $Y_{SX}^{\max}$ must be calculated from the slope of the curve under carbon and energy limitation. The experimental data indeed often show a linear relationship. In such cases it is assumed that q_m is a constant. However, sometimes a straight line is not obtained. It is clear that in such a case Pirt's concept does not hold. An essential assumption, which was previously not formulated explicitly, is that Pirt's concept can only be applied when growth is energy-limited. This means that under other limitations the "apparent" q_m may have a variable value (see Fig. 4), and does not refer to the "minimum" energy required for maintenance of the integrity of the living cell. In practice, energy limitation often involves growth-limiting amounts of an organic compound that is simultaneously the energy and carbon source. With limitations other than energy

Fig. 4 Relationship between the specific growth rate and the specific rate of oxygen consumption in variously limited chemostat cultures of *Klebsiella aerogenes* growing in a glucose-containing medium. Cultures were, respectively, carbon-limited (▲), NH_3 -limited (△), SO_4^{2-} -limited (●), and phosphate-limited (○). Reproduced from Neijssel, O. M. and Tempest, D. W. (1976). Bioenergetic aspects of aerobic growth of *Klebsiella aerogenes* NCTC-418 in carbon-limited and carbon-sufficient chemostat culture. *Archives of Microbiology*, 107, 215–221.

Fig. 5 Carbohydrate content of *Torula utilis* as a function of growth rate and limiting nutrient (unpublished data of Herbert and Tempest). The organism was grown in a continuous culture at a number of different growth rates in a glucose- NH_3 -salts medium (A) with glucose as limiting nutrient, and (B) with NH_3 as limiting nutrient. Dry weight of cells in the culture and their total carbohydrate content (anthrone method), as well as steady-state levels of glucose and NH_3 in the culture, are plotted against growth rate. Reproduced from Herbert, D. (1961). The chemical composition of microorganism as a function of their environment. In: Meynell, G. G. and Goeder, H. (eds.) *Microbial reaction to environment: 11th symposium*, pp. 391–416. Reading: Society of General Microbiology: Cambridge University Press.

(and carbon), much higher consumptions may be observed as glucose may be consumed for purposes other than growth. This is very well described in the literature for microorganisms grown under nitrogen (ammonium) limitation, and is demonstrated in Fig. 5 from an experiment with *Torula* (*Candida*) *utilis*, grown under nitrogen limitation. At low growth rates, the cell will store reserve material that does not contain nitrogen (e.g., polyglucose or poly- β -hydroxybutyrate), because the cell has an excess of carbon and energy. This phenomenon is quite common and may have ecological implications, because if a shortage of energy and/or carbon sources occurs, the cell can then use the stored reserve material. This ability of a cell to consume more substrate than strictly necessary for the synthesis of “standard” cell material is based upon the surplus capacity of the respiratory system under substrate excess. This will be further discussed later.

The consequence of the introduction of the maintenance energy requirement is that the empirical Monod model for growth no longer holds. If maintenance energy is playing a role, then clearly a discrete rate of substrate supply and/or consumption can take place without growth, when the rate of supply is lower than required for maintenance purposes. This implies that the Monod type of saturation curve (hyperbola Eq. (1)) must be written for q_s rather than for μ :

$$q_s = q_{\max} \frac{C_s}{K_s + C_s} \quad (17)$$

This is the formula commonly used in computer models to calculate K_s from (weighted) experimental data.

After rearrangements of Eq. (17) one obtains an alternative formulation for μ :

$$\mu = \mu_{\max} \frac{C_s}{K_s + C_s} - \frac{K_s}{K_s + C_s} Y_{\text{SX}}^{\max} q_m \quad (18)$$

This equation shows that at $C_s = 0$, $\mu = -q_m Y_{\text{SX}}^{\max}$, while at $C_s = \infty$, $\mu = \mu_{\max}$. This equation is the Monod equation in the first part, corrected with a term that becomes zero at very high C_s . Accounting for maintenance, the formulae for the steady state of C_X and C_S become

$$\bar{C}_X = \frac{[DY_{\text{SX}}^{\max}(C_{\text{Si}} - C_s)]}{D + q_m Y_{\text{SX}}^{\max}} \quad (19)$$

$$\bar{C}_S = \frac{(D + q_m Y_{\text{SX}}^{\max})K_s}{[Y_{\text{SX}}^{\max}(q_s^{\max} - q_m)] - D} \quad (20)$$

Fig. 3 has been constructed from Eqs. (19) and (20), using assumed kinetic parameters: $Y_{\text{SX}}^{\max}$, C_{Si} , $q_s^{\max}$, q_m , and K_s . Further considerations concerning the maintenance energy requirement will be discussed under the physiological studies.

In continuous culture experiments, many other deviations from the theoretical behavior of chemostat cultures can be found. For example, if the cells present in the culture are not all viable (i.e., if a certain percentage of cells continuously die), a deviation will appear because the living cells must grow faster than D to maintain the value of C_X . Another problem might be the toxicity of the growth-limiting substrate, which could give deviation at high D (i.e., high $\bar{C}_S$). Mathematical models incorporating these extra variables can be found in the literature.

In the laboratory practice there are a number of potential problems related to the growth of microorganisms in the chemostat. In homogeneities may often occur because the culture is not well stirred, or because wall growth takes place.

Computer modeling of the chemostat operation. The Eq. (17) for the specific consumption rate of the (limiting) substrate and Eq. (16), combined with two balance equations for substrate and biomass, respectively, are commonly used in the engineering treatment and modeling of the chemostat operation. The two balance equations are similar to Eqs. (7) and (8), but in Eq. (7) the specific growth rate μ is replaced by the specific consumption rate q_s . This allows the description of the growth and substrate consumption of a specific microorganism both in steady state and in nonsteady state when the culture is started up. Recently, Hakkaart et al. (2017) have published a paper describing a "Simulator-assisted workshop for teaching the chemostat." Using the four equations they developed a MATLAB based program ("Chemostatus") visualizing key parameters (i.e. biomass, substrate concentrations) of simulated chemostat cultures from start-up growth conditions to steady state. The workshop has successfully been used by these authors to teach quantitative microbial physiology. The files of the Chemostatus are freely available and the simulator can be requested at HYPERLINK "mailto:chemostatus@gmail.com" chemostatus@gmail.com.

Continuous Cultivation by Other Controls: The Turbidostat and pH-Auxostat

The flow-controlled chemostat is not suited for the growth of microorganisms at a value μ near D_C ($\approx \mu_{\max}$). Small experimental errors in the pumping rate, and hence in the D , will have dramatic effects on $\bar{C}_X$ (see Fig. 1). In such a case, a turbidostat is preferred. In a turbidostat, the density (turbidity) of the culture is measured continuously and kept constant by a proportional adjustment of the pumping rate. A practical problem is that the measuring device, such as a flow-through cell in a spectrophotometer, used to measure the turbidity and generate the feedback to the pump can easily be fouled by wall growth.

Other types of continuous cultures are controlled by monitoring a variety of measurable chemical or physical parameters and appropriate feedback. Examples are carbon dioxide, sulfide, light, oxygen, and protons (i.e., pH). Such systems are called "auxostats." The pH-auxostat has frequently and successfully been used in practice. The theory is as follows. Assuming that during growth protons (H^+) are excreted into the culture liquid, the change in their concentration as a function of time can be expressed as follows:

$$\frac{dH^+}{dt} = \mu C_X h + D[H_R^+] - D[H_C^+] - DB_R \quad (21)$$

where h is the stoichiometry of proton formation per gram dry weight of cells (moles (g DW) $^{-1}$), $[H_R^+]$ the proton concentration in the medium reservoir (moles l^{-1}), $[H_C^+]$ the proton concentration in the culture (moles l^{-1}), and B_R the buffer capacity of the reservoir medium (moles l^{-1}). For the simplest situation, in which only a small difference exists between the pH of the medium and that of the culture, Eq. (21) reduces to

$$\frac{dH^+}{dt} = \mu C_X h - DB_R \quad (22)$$

and in steady state with $\mu = D$ the following expression for cell density is the result:

$$\bar{C}_X = \frac{B_R}{h} \quad (23)$$

This shows that the steady-state cell density is a linear function of the buffering capacity of the medium, assuming that h is independent of B_R . Combining Eq. (21) with the general nutrient balance for continuous culture Eq. (7) yields the following expression for $\bar{C}_S$ in steady-state cultures:

$$\bar{C}_S = C_{Si} - \frac{B_R}{hY''_{SX}} \quad (24)$$

Finally, solving the conventional Monod expression (Eq. (1)) for the obtained steady-state values of $\bar{C}_S$ allows a plot of the specific growth rate (μ), the steady-state substrate concentration ($\bar{C}_S$), and the steady-state cell density ($\bar{C}_X$) as a function of the buffering capacity (B_R) (Fig. 6). As can be seen from this illustration, the specific growth rate of the cells remain at a value close to $\mu_{\max}$ over a large range of buffering capacities but, of course, will decrease at high buffering capacities due to the decreasing concentration of remaining growth substrate. Obviously, this effect will be most prominent with cells possessing relatively high K_S values for the substrate used. In principle, this will provide the opportunity to choose the buffering capacity such that the substrate concentration becomes strongly growth rate-limiting, thus creating an overlap with the conventional mode of substrate-limited growth.

Fig. 6 Major growth parameters in a pH-auxostat. Residual substrate concentration C_s (moles L^{-1}), specific growth rate μ (h^{-1}) and cell density C_x (g DW L^{-1}) as a function of the buffering capacity B_R (moles L^{-1}), in the reservoir medium. Arbitrarily chosen values: $Y_{sx}'' = 22$ (g DW (mole) $^{-1}$), $h = 0.05$ (moles (g DW) $^{-1}$), $C_{si} = 10$ (mole L^{-1}) and $\mu_{max} = 1$ (h^{-1}). Adapted from Gottschall, J. C. (2000). Continuous culture. In: Lederberg, J. (ed.) *Encyclopedia of microbiology*, 2nd edn, vol. 1, pp. 873–886. New York: Academic Press Inc.

Continuous Cultivation in the Retentostat or Recycling Chemostat

The chemostat is recommended to cultivate microorganism at submaximal specific growth rates. The technique can be used to grow pure cultures of microorganisms, or to enrich for microorganisms at low growth rates, that is, low substrate concentrations. In practice dilutions rate between 0.005 and 1.0 h^{-1} have been used with chemostats of 1–2 L working volume. However the chemostat clearly has its technical limits when it comes to very low rates of growth and/or substrate supply, since the low flow of nutrients will cause fluctuations in the limiting substrate in the first place due to the drop size of the incoming medium and also to the potential effect of wall growth. An excellent tool to circumvent this problem is the use of a recycling- or retention-chemostat, in which part of the biomass is retained in the culture by using a membrane that keeps the microorganisms in the chemostat, but filters out the spent medium. Examples and suitable mathematical models will be cited in the following sections.

Competition of Microorganisms for a Growth-Limiting Substrate

Consider microorganisms A and B, which have μ - C_s curves of the types presented in Fig. 7A and B. In the example shown, if organisms A and B are grown in batch culture (with a maximum specific growth rate of μ_{max}), organism A will grow faster than organism B in both cases and therefore becomes dominant (assuming that both have started with equal numbers and neither has a lag phase). In the example shown in Fig. 7B, however, if A and B are grown together in a continuous culture with growth limitation by substrate C_s , then, at low D , organism B will dominate. This can be rationalized by assuming a steady state with organism B at

Fig. 7 The μ - C_s relationship of two organisms A and B (A) $K_S^A < K_S^B$ and $\mu_{max}^A > \mu_{max}^B$; (B) $K_S^A > K_S^B$ and $\mu_{max}^A > \mu_{max}^B$.

$D = 1/2\mu_{\max}^B$. The steady-state concentration of the growth-limiting substrate would be equal to K_S^B . At that nutrient concentration, organism A will grow at a $\mu < D$, and hence it will be washed out. Conversely, if we would have a steady state of organism A at that same D , organism B would be able to grow faster at the concentration of the growth-limiting nutrient than A, and hence would out-compete (replace) organism A. In other words, in spite of the lower $\mu_{\max}$ of B shown in Fig. 7B, this organism will grow faster than organism A at low $\bar{C}_S$. In fact, it is the slope of each of the curves, that is $\mu_{\max}/K_S$, which determines the outcome of the competition. This slope is often referred to as the “affinity” for the substrate. A high affinity, in other words, will equip the organism with the ability to grow relatively fast at very low nutrient concentrations. This is most relevant to the (semi)natural environment. In the later examples of competition for growth-limiting nutrients, we will not only refer to mixtures of different organisms, but also to competition between mutants of one species, which is very important for the general study of selection. However, mutant selection is also a potential practical problem in the continuous cultivation of pure cultures in the laboratory (see below).

Physiological and Functional Genomic Studies with the Chemostat

Physiological Studies

As pointed out in the introduction, the chemostat is a unique tool for the study of the physiology of microorganisms at different growth rates and with different growth limitations under controlled, nutrient-limited conditions. For example, by means of this technique it has been found that the composition of the cell changes strongly, both qualitatively and quantitatively, with changing growth rates and with the type of growth limitation. At low growth rates, cells appear to possess fewer ribosomes (rRNA) than at higher growth rates. This can be directly related to the requirement of the cell to synthesize protein more rapidly when growing fast as the rate of protein synthesis per ribosome is about constant. Especially when growth is limited by the carbon and energy source, the amount of catabolic enzymes (for energy production) present in the cell may be observed to increase with increasing growth rate. Furthermore, the amount of cytochromes in a cell also often increases or decreases in response to environmental changes. However, a general rule for alterations in enzyme activity with changing growth rate cannot be given, because these changes are usually the result of very complex regulatory mechanisms.

Metabolic pathways and growth rates: As already stated, the chemostat is used for the study of all forms of limitation. Examples involving nitrogen and carbon/energy supplies as well as different limitations will be discussed here.

Most organisms grown in batch culture with ammonia as the nitrogen source possess glutamate dehydrogenase for ammonia assimilation. The same enzyme is used by chemostat cultures under limitation by the carbon and energy source. However, if growth is limited by ammonia, the combination of glutamate oxoglutarate aminotransferase and glutamine synthetase (the GOGAT-GS system) is induced. The latter enzyme has a considerably lower K_m value for ammonia than does glutamate dehydrogenase (about a factor of 5–10). The assimilation of ammonia through glutamine synthetase costs 1 ATP, but it is clear that under conditions of energy excess, this is not a problem for the cell.

While the biomass yield is, of course, dependent on the substrate (as is the case in batch culture), it is also dependent on the metabolic pathway used by the organism, which in turn may be dependent on the growth rate. The group of Stouthamer has observed a very interesting example. They found that at high growth rates *Lactobacillus casei* ferments glucose, producing lactate. Accordingly, when grown in the chemostat under glucose limitation at high D values, the bacterium produced only lactate. However, when D was lowered, the density of the culture increased and acetate appeared in the culture. The explanation of this phenomenon is that at low D values *L. casei* can make additional ATP by converting pyruvate into acetyl CoA rather than lactate. By means of a phosphoroclastic splitting of acetyl CoA, one additional ATP is formed. To keep a proper redox balance the organism produces formate and ethanol:

There is no definite answer to the question of why the organism at high growth rates does not also produce energy from glucose as economically as possible. It is possibly due to the fact that the reaction that yields 3 ATP is not fast enough for higher growth rates. It was found that the lactate dehydrogenase is activated by fructose-1,6-biphosphate. At low growth rates the concentration of this intermediate is low and the lactate dehydrogenase does not function. In this situation, the pyruvate can be converted into formate, ethanol, and acetate.

Neijssel and Tempest studied the response of *Klebsiella aerogenes* grown fully aerobically under different limitations in the chemostat with glucose as the only carbon and energy source as shown in Fig. 4, which is discussed in the theory section. The specific oxygen respiration rate qO_2 was recorded as a function of D and in all cases a linear relation existed. In the carbon-limited cultures glucose was completely consumed, but in all other (glucose-sufficient) cultures the sugar was partially respired and also partially fermented, as indicated by the appearance of different products such as gluconate and acetate (not shown in Fig. 4). In many

publications, it is also shown that under limitations other than by the carbon and energy source the cell-composition changed as mentioned for nitrogen limitation. For example, during phosphate or sulfate limitation the cell may synthesize alternative cell wall components not containing the limiting nutrient.

As mentioned earlier, according to the Pirt maintenance concept the extrapolated consumption rate under carbon and energy limitation at $D = 0$ represents the true maintenance energy requirement, q_m . Extrapolation of the other lines to $D = 0$ simply demonstrates that the organism respire more glucose than required for biosynthesis. The apparently wasteful use of glucose under the other limitations may in part be due to the need for more energy for transport of the limiting nutrients, but the authors also clearly showed that a certain uncoupling of energy metabolism and biosynthesis occurred. The interpretation of this phenomenon is that under the other limitations the organism is unable to match (excess) uptake of glucose with the requirement for growth, and hence must waste energy since without it, it would be unable to maintain the proper energy charge and redox balance in the cell. Neijssel and Tempest argue that the maintenance energy requirement is not necessarily limited to the Pirt-type μ -independent maintenance requirement, but may be in part growth rate dependent in a linear manner. The discussion of this point falls beyond the scope of this article. The physiology of maintenance requirement has been studied in "retentostats" with full biomass retention/recycling of pure cultures of organisms that have relatively high maximum specific growth rates (Van Verseveld et al., 1986; Boender et al., 2009).

Yields under fluctuating-nutrient supply: Another point that deserves attention is that energy-limited cultures, when exposed to sudden increases of their limiting energy source, often show lower yields. For example, when glucose-limited cultures of the yeast *Saccharomyces cerevisiae* were given the same amount of glucose per unit of time, but in discrete pulses, rather than continuously, the experimental biomass yield decreased. Directly after the pulse the yeast would excrete ethanol, which would be rapidly consumed again once all glucose had been taken up. The ethanol consumption was proceeding through acetate, which was transiently observed. Before the next pulse of glucose appeared all substrates had been converted into CO_2 or taken up into biomass. Apparently under these conditions, the (excess) uptake of glucose could not be met by biosynthesis, and a certain uncoupling of energy metabolism and biosynthesis would take place and some substrate was wasted as heat. This phenomenon was not observed in the yeast *Candida utilis*, which under these fluctuating conditions would control its glucose uptake to match the requirement for biosynthesis, and hence in the latter case the yields were the same.

Functional Genomic Applications of the Chemostat

With the booming interest in "functional genomics" and "systems biology" of microbes, which may well be considered as a modern version of microbial physiology, the chemostat has obtained renewed interest not only because it allows one to study the (controlled) response of an organism to different limitations, but also because of the reproducibility of the experiments. This was put to the test by the groups of Pronk and Nielsen, who did a transcriptome analysis of *S. cerevisiae* grown in the chemostat under both aerobic and anaerobic conditions in two independent laboratories. Using triplicate experiments in each laboratory and adequate statistical analysis, they were able to show 95% agreement for transcripts that changed by more than twofold. This is remarkably reproducible for these types of biological experiments and shows the great values of the use of the chemostat for genomic research. The Pronk group also used the chemostat to grow the same organism under carbon, nitrogen, phosphorous, and sulfur limitations at the same dilution rate. In doing so, they could rule out that major differences would be caused by differences in specific growth rate. Experimental design and medium composition were carefully checked to ensure that the chosen growth limitation was realized. They observed that 31% of the annotated genome transcripts changed significantly in these experiments with four separate limitations. Nearly 500 transcripts could specifically be linked to one of the four nutrient limitations. Fifty-one genes showed tenfold changes under one particular limitation. They concluded that the responsible genes may be targets for future diagnostic study and characterization of specific limitations for metabolic engineering strategies. For the cultivation of industrially relevant organisms the use of poorly defined, complex media (such as molasses) is common and hence this type of analysis would be most important. These two examples underline the power and usefulness of controlled cultivation in the chemostat for reproducible and quantitative functional genomic research.

Simultaneous Use of Mixed Substrates in Continuous Culture

Equivalent Substrates

Diauxic growth is a phenomenon that can be observed when, for example, *Escherichia coli* is grown in batch culture on a mixture of glucose and lactose. Growth of the culture clearly shows two phases: first the glucose is consumed and, after a lag phase, the lactose can then be used.

At high glucose concentrations the organism grows at the maximal rate and lactose metabolism is repressed (known as catabolite repression). This is because lactose transport is inhibited at high-energy status of the phosphotransferase (PTS) system. It should be remembered that the PTS system is in dynamic equilibrium with the PMF and the energy charge of the cell. Under simultaneous limitation of growth by glucose and lactose in a continuous culture, at relatively low dilution rate ($D = \mu$), the energy status of the cell is relatively low and the use of lactose does not appear to be repressed. Thus at low D values, the simultaneous use of both compounds occurs, whereas at high D values lactose does appear in the fermentation broth. In *E. coli*, $\mu_{\max(\text{glucose})}$ is approximately 1.0 h^{-1} , while the $\mu_{\max(\text{lactose})}$ is approximately 0.8 h^{-1} . In this case, the complete simultaneous use occurs below $D = 0.5 \text{ h}^{-1}$, and

Fig. 8 Steady-state concentrations of glucose (□) and galactose (■) during growth of *E. coli* at a constant dilution rate of 0.30 h^{-1} in carbon-limited chemostat culture with different mixtures of two sugars. The proportion of the sugars in the mixture fed to the culture is given as weight percentages. The total sugar concentration in the feed was held at 100 mg L^{-1} . Reproduced from Egli, T. (1995). The ecological and physiological significance of the growth of heterotrophic microorganisms with mixtures of substrates. In: Jones, J. G. (ed.) *Advances in microbial ecology*, vol. 14, pp. 305–386. New York: Plenum Press.

glucose and lactose are detectable only at microgram per liter levels. Between $D = 0.5$ and 0.8 h^{-1} lactose gradually appears at increasing levels and a plot of C_s (lactose) against D shows a normal Monod relation as shown in Fig. 1. Above $D = 0.8 \text{ h}^{-1}$ lactose is no longer used and the organism shows typical diauxic behavior as in batch culture with excess glucose. The culture was washed out above the D_c for glucose, and hence also for the glucose the organism displayed normal Monod kinetics (Fig. 1).

The group of Egli has performed similar experiments with other (two or three) mixtures of sugars, for example glucose and galactose, which they were able to measure directly in the steady-state culture liquid at extremely low levels using a new sensitive assay. Fig. 8 shows the results of chemostat experiments run at $D = 0.3 \text{ h}^{-1}$ with different ratios of glucose (0–100%) and galactose (100–0%) in the in-flowing medium.

It can be seen that the residual, steady-state concentration of each of the two growth-limiting substrates was lower in the presence of the second substrate than in its absence. In a 50:50 mixture the residual sugar concentrations were around 20 µg L^{-1} ($\approx 100 \text{ nmol L}^{-1}$), that is, almost half of that compared with the presence of one substrate only. This important observation, predicted by mathematical modeling, indicates that in the competition for substrates in Nature, the capability to use substrates simultaneously has a competitive advantage (also see the paragraph on competition for mixed substrates).

The simultaneous, that is mixotrophic, use of substrates with similar roles in metabolism is not limited to sugars but also applies to all kinds of mixtures of carbon and energy sources, mixtures of organic compounds and inorganic energy sources, as well as to mixtures of nitrogen sources, such as ammonium and nitrate. Likewise, the same mixotrophic behavior occurs with respect to electron acceptors such as limiting mixtures of oxygen and nitrate. An extensive study in this area has been done by Gottschal and Kuenen on mixotrophic growth of a facultative sulfur-oxidizing bacterium, *Thiobacillus versutus* (presently named *Paracoccus versutus*) on a mixture of acetate and thiosulfate as an additional energy source and/or CO_2 as an additional carbon source. The organism showed typical diauxic behavior in batch culture at high acetate (consumed first) and thiosulfate, but under simultaneous limitation (at $D = 0.05 \text{ h}^{-1}$) by the two substrates both were used simultaneously. With high acetate to thiosulfate ratio the latter substrate served as supplementary energy source, while at low ratio acetate was primarily used as carbon source with CO_2 as supplementary carbon source for autotrophic metabolism. Thus a remarkably efficient metabolic control and use of resources were revealed, which made this organism very competitive under conditions of mixed-substrate supply and/or short-term fluctuation in the supply of the separate substrates.

Simultaneous Limitation by Nonequivalent Substrates

When in a carbon-limited culture the in-flowing nitrogen (originally in excess) is lowered, the residual nitrogen in the culture will go down. At a stage where, academically speaking, the nitrogen is still in slight excess the organism may, however, begin to induce its high-affinity GS-GOGAT system for ammonium assimilation and hence employ the ATP-requiring assimilation pathway, in spite of its carbon and energy limitation. This was experimentally verified by Egli, who showed that below suboptimal nitrogen content in the in-flowing medium the organism displays an actual physiological double limitation.

A recent study by Ihssen and Egli with glucose-limited *E. coli* cultures confirmed and extended the generally observed phenomenon of de-repression of pathways in the lower D -range. Under single limitation by glucose at $D = 0.3 \text{ h}^{-1}$ (i.e., at 40%

of $\mu_{\max}$) a large number of metabolic pathways were de-repressed, without the inducer being present, in contrast to what is observed in batch culture. These cultures can metabolize and grow instantaneously on the new substrates, such as sugars, alcohols, and organic acids. It is generally believed that this type of response offers an advantage for survival because it reduces the time required to react to a change in nutrient supply. Clearly under natural conditions, mixed substrates will be available and mixotrophic growth on a variety of substrates will be the rule rather than the exception. In these experiments, the authors ensured that the selection of particular mutants did not play a significant role. This was accomplished in practice by establishing each steady state from a fresh inoculum.

Ecological Studies in the Chemostat

General Considerations

In Nature and in man-made environments such as wastewater-treatment plants, concentrations of nutrients are generally very low. The order of magnitude is usually in the nanomolar (microgram per liter) level and K_S values of organisms are adapted to these low concentrations. The physiological or competitive behavior of organisms at these low levels can be studied by using chemostat cultures grown under the appropriate limitation. It is true that in Nature actual steady states rarely occur but the chemostat is an excellent tool to look at the principles of (eco)physiological response and competition, under controlled conditions. In addition, continuous cultivation in chemostat equipment under dynamic condition can also be done for simulation of natural conditions, though the mathematics of such operations is much more complicated.

The groups of Jannasch and Veldkamp have extensively studied the competition of bacteria under nutrient limitation in the chemostat. It appears that in nature there are many organisms of type B (Fig. 7B), which possess a high affinity for a growth-limiting nutrient (i.e., low K_S combined with a relatively low $\mu_{\max}$) for the substrate. An example is that of a rod-shaped bacterium (R) and a spirillum (S) as shown in Fig. 9.

Both strains were originally isolated from phosphate-limited continuous cultures inoculated with ditch water. One chemostat was run at a high D , with a second one at a low D . In the culture with the low D the spirillum became dominant, while in the culture with the high D the rod dominated. When the two pure cultures were mixed, and cultivated again at the same D values, the cultures appeared to behave like the original chemostat enrichments. When experiments were performed with the same set of two organisms under other nutrient limitations, that is, succinate, ammonium, or potassium, very similar crossing curves were obtained showing that the spirillum had a generally higher affinity for substrates than the rod. This property, which points to a generally higher transport capability at low nutrient concentration, is linked to the much higher surface to volume ratio of the spirillum. This allows the accommodation of more membrane-transport proteins per unit of biomass.

Competition for Mixed Substrates

In nature many growth-limiting substrates are available simultaneously, and hence an understanding of the selection and competition for more than one substrate has also been studied in the chemostat. Unquestionably, other abiotic and biotic variables also play a role in the establishment of a community of organisms in any environment. Theoretical calculations by Fredrickson indicate that the maximum number of coexisting species is determined by the number of variables in a particular environment. As a simple example, a steady state with two growth-limiting substrates will allow a maximum of two existing species in the culture. When a variation of the pH would be admitted as a third variable, the number would increase to a maximum of three.

Fig. 9 Specific growth rate of fresh water rod-shaped bacterium (R) and a spirillum (S) as a function of phosphate concentration. The curves are schematic and based on two measurements each at the growth rates indicated by the arrows. K_S values: rod-shaped bacterium, $6.6 \times 10^8 \text{ mol L}^{-1}$; spirillum, $2.7 \times 10^8 \text{ mol L}^{-1}$. Reproduced from Kuenen, J. G., Boonstra, J., Schroder, H. G. J., and Veldkamp, H. (1977). Competition for inorganic substrates among chemoorganotrophic and chemolithotrophic bacteria. *Microbial Ecology*, 3, 119–130.

Table 1 Maximum specific growth rates of two specialists and one versatile bacterium.^a

Organism	Lifestyle	Relevant physiology	$\mu_{\max}$ thiosulfate (T)	$\mu_{\max}$ acetate (A)	$\mu_{\max}$ (T + A)
<i>Thiobacillus neapolitanus</i>	Specialist	Obligate chemolithoautotroph	0.35	0	0.35
<i>Thiobacillus versutus</i>	Versatile	Facultative	0.1	0.22	0.22
Heterotroph G7	Specialist	Obligate heterotroph	0	0.43	0.43

^aThe specialists can only grow on a single specific substrate. The versatile organism shows diauxic behavior towards thiosulfate, but simultaneously consumes acetate and thiosulfate in the chemostat at low $D = 0.05 \text{ h}^{-1}$.

Gottschal and colleagues published an interesting example of a set of three organisms competing for two substrates. The properties of the three organisms are listed in Table 1 and refer to *Thiobacillus neapolitanus*, *T. versutus*, strain A2, and Spirillum G7.

T. neapolitanus (presently known as *Halothiobacillus neapolitanus*) is a specialized, obligately chemolithoautotrophic sulfur oxidizer, which can grow only on an inorganic sulfur compound (thiosulfate) as the energy source and CO_2 as carbon source. Spirillum G7 is a specialized chemoorganoheterotroph, which can grow only on acetate as carbon and energy source. Both specialists have a high $\mu_{\max}$ in batch (excess substrate) on their respective substrates. In contrast, *T. versutus*, presently known as *P. versutus*, is a facultative organism capable of growing in both modes, but at lower $\mu_{\max}$ in batch. As mentioned above, when grown in a mixture of the two substrates in batch culture at high substrate concentrations, the organism shows diauxic behavior and consumes acetate first and then thiosulfate. Therefore, $\mu_{\max}$ (T + A) does not increase. When a mixture of the three organisms is inoculated in excess acetate and thiosulfate in batch culture, we end up with a dominant mixture of the two specialists. However under limitation by a mixture of acetate and thiosulfate at a low dilution rate in the chemostat, the versatile organism can very effectively use the two substrates simultaneously. It was shown that, as a result of this capability at low D (0.05 h^{-1}) it can coexist or even out-compete the two specialists in a mixed culture of the three organisms. This is due to the fact that in the mixture of the second substrate (thiosulfate or acetate) the versatile organism can lower the concentration of the other limiting nutrient, as was shown above for the mixture of glucose and galactose (Fig. 8) and mathematically modeled by Gottschal and Thingstad. In line with theoretical predictions concerning the maximum number of coexisting species in relation to the number of variables, it was shown that *T. versutus* was able to maintain itself at low number in the steady-state culture of *T. neapolitanus*, in spite of its lower affinity for thiosulfate, since the specialist excreted glycollate. The glycollate was mixotrophically consumed by the versatile organism. This demonstrates the important principle that metabolic (excretion) products can not only lead to simple cometabolic consumption of this product by a second population, but that by excreting a consumable product the excreting organism may generate more competition for its main substrate.

Continuous cultivation not only provides a tool to create reproducible steady-state cultures, but also offers controlled alternations of environmental and nutritional conditions, such as feast and famine cycles, changes of substrates, or temperature. In such experiments, a true steady state is not established but nevertheless highly reproducible cycles will allow the precise monitoring of the response of the organism(s). Indeed in the case of the two specialists and the versatile organism, it was shown that the latter could also out-compete the two specialists at low D when acetate and thiosulfate were alternately supplied. As long as the period of the cycle was below 4 h the versatile organism would continue growing, but when longer cycle times were introduced the versatile organism would repress its autotrophic potential too far down to be able to compete with the specialists in the next cycle. This example serves to emphasize the usefulness of continuous cultivation for ecophysiological research.

Industrial Applications of Continuous Culture

In the industrial production of (secondary) metabolites, such as antibiotics, the production organism (i.e., a fungus like a *Penicillium* or a *Streptomyces* sp.) is cultivated at submaximal μ , because only under these conditions will the organism produce at a sufficiently high rate. Clearly for optimization reasons, it is essential to study the performance of the organism in the chemostat at different dilution rates. The production process is, however, rarely performed in continuous culture. The main reasons for this are: (1) the cell density and hence the product concentration can never be very high because the aeration capacity of the fermentors have limited oxygen transfer and cooling capacities. This leads to insufficiently high product concentrations for economical down-stream processing. (2) The inevitable selection of less productive spontaneous mutants under the imposed carbon and energy limitation (see below). Therefore, in industry, the cultivation method of choice is usually fed-batch cultivation. After an initial stage of growth in excess substrate the organism is fed (in batch) with a concentrated feed of the growth-limiting nutrient (i.e., glucose or ammonium) in such a way that the instantaneous consumption of the added nutrient limits the growth of the organism. Using this method, high product concentrations may be reached and in the short-term cultivation period mutants will not become dominant.

In the practice of wastewater treatment many (semi) continuous operations are used, be it that biomass retention and recycling of biomass are practiced. An example of a chemostat-type large-scale process is the production of a 50:50 ammonium/nitrite mixture from ammonium-containing reject water using selected, oxygen-limited mixed cultures of nitrifying bacteria. The effluent is used to feed an anaerobic anammox reactor, which converts the mixture into nitrogen gas as demonstrated by Van Dongen and

colleagues. The recycling chemostat with major biomass recycle has been used to grow (mixtures) of microorganisms at a constant very low growth rate, down to 0.05/day. This has been particularly successful for enrichment of very slow growing microorganisms from natural resources and from wastewater treatment plants (Van der Star et al., 2008).

Competition and Selection of Mutants in the Chemostat

Nutrient-Limited Wild Types and Mutants

A monoclonal bacterial culture will contain mutants. It is known that the average number of mutants for a particular gene is of the order of 1 out of every 10^6 – 10^9 replications. This means that mutants, which can perform better under nutrient limitation than any wild-type organism, may out-compete the parent strain. Therefore, the study of competition and selection does not require two different species. The technique is sometimes intentionally utilized to isolate mutants, which by spontaneous (or induced) mutation have obtained a competitive advantage. A classical example of this is the development of a constitutive mutant for β -galactosidase of *E. coli* in a lactose-limited culture as described by Novick. Once the constitutive mutant has been enriched, so-called super-constitutive mutants, which produce more β -galactosidase often arise. This is illustrated in Figs. 10 and 11.

These results can be understood by making the assumption that the uptake of lactose (and the linked conversion of lactose into galactose and glucose) is the rate-limiting step. By producing more permease and β -galactosidase (which is transcribed under the same promoter), the cell would be able to convert lactose somewhat faster at the same $\bar{C}_s$. For example, as long as the lactose permease is the real bottleneck in the rate of metabolism of lactose, a doubling of the permease concentration will allow the organism to maintain the same overall rate at half the concentration of the lactose. Consequently, it will be able to grow at the same rate at half the lactose concentration and hence out-compete the wild type. Consequently, the μ - C_s curve of the mutants changes. This is illustrated in Fig. 11, where Novick has given the wild-type μ - C_s curve an "S"-shape to accommodate the fact that, in contrast to the constitutive mutant, it requires a relatively high concentration of lactose to fully initiate transcription of the lactose operon.

Fig. 10 Increase in β -galactosidase activity of *Escherichia coli* strain E-102 grown in a lactose-limited chemostat. Reproduced from Novick, A. (1961). Bacteria with high levels of specific enzymes. In: Zarrow, M. X. (ed.) *Growth in living systems, purdue growth symposium*, pp. 93–106. New York: Basic Books, Inc.

Fig. 11 Hypothetical relationship between growth rate and lactose concentration when the growth-limiting enzyme is constitutive and when it is inducible. Reproduced from Novick, A. (1961). Bacteria with high levels of specific enzymes. In: Zarrow, M. X. (ed.) *Growth in living systems, purdue growth symposium*, pp. 93–106. New York: Basic Books, Inc.

In the above case, 25–30% of the total protein of the “super-constitutive” mutant appeared to be β -galactosidase. This mutant is, in fact, extremely vulnerable, competitively, under any other form of growth limitation since then the overproduction of the enzyme would be a waste of energy. For this reason, if this culture is transferred to glucose limitation, other mutants, which cannot be distinguished from the original (wild type) parent strain, will rapidly appear. In summary, the striking changes shown in the final mutant demonstrate the extreme selective forces that can be exploited in the chemostat to obtain mutants that have taken advantage of the chosen limitation. For a representative set of other examples the reader is referred to the reviews by Kuenen and Harder and Sikyta.

Egli's team has studied the selection of mutants of *E. coli* in glucose-limited chemostats. With a combination of highly sensitive analytical tools for residual sugar concentrations as well as the availability of tools for physiological screening, a thorough analysis has been made of the events taking place during the selection of *E. coli* mutants under glucose limitation in the chemostat. It appeared that the selection events were consistent with Monod kinetics. Consecutive mutants, with higher affinity (i.e., a mutation leading to either higher $\mu_{\max}$ or lower K_s) for glucose, gradually took over in the chemostat, as evidenced by the stepwise drop in the residual glucose concentration in the culture. Initially $\mu_{\max}$ improved, but this stopped after the first 150 h and then further improvements were primarily due to the lowering of the K_s . The experiments were reproducible in cultures with high number of cells in the culture (10^{11}), that is, the stepwise improvement could be predicted. However at low numbers of total cells (10^7), the mutation frequency for advantageous mutations (estimated to be $1/10^7$ cell duplications) caused a stochastic behavior. Evidently, at 10^{11} cells per culture, in the order of 10^4 favorable mutants would have been present after the first generation and the system did not have to wait for favorable mutants to overgrow the existing population. Over the time span of 500 h in these experiments, no mutant types other than the high-affinity strains established themselves in the culture. They obtained no evidence for the establishment of secondary populations of mutants with a lower affinity for glucose, as was observed by Rosenzweig et al. (1994), after long-term selection at $D = 0.2 \text{ h}^{-1}$. In this experiment, a mixture of mutants had been selected with a distribution of tasks after 773 generations (2500 h). This mixed culture remained essentially the same for an additional 450 generations. One dominant mutant had the highest affinity for glucose but excreted glycerol and acetate, which were consumed by a second and third (satellite) mutant, respectively. Hence under the extreme and permanent selection conditions, the distribution of tasks in the breakdown of glucose (“resource partitioning”) apparently was the most effective way to deal with the regulatory consequences of metabolic rearrangement in the respective mutants. Although the exact steady-state fluxes of glycerol and acetate in the chemostat were not known, it must be assumed that the second and third mutants, having the capacity for glucose metabolism, were both growing mixotrophically on glucose and glycerol or acetate, respectively.

The selection of mutants in nutrient-limited chemostat has extensively been studied by the group of Ferenci and colleagues, who showed that depending of the type of limitation a different spectrum of mutants is continuously produced and maintained in the chemostat which results in the selection (“evolution”) of different types of mutants over time. They studied carbon, phosphate, nitrogen, oxygen or iron limited chemostat cultures of *E. coli* and observed a number of different types of mutation caused by base pair changes, transposition or indel changes that occurred at different frequencies and preferences under the influence of the specific limitation, demonstrating that the environment not only influences selection but also genetic variation.

Research by Stevenson and Schmidt on batch and chemostat grown *E. coli* has shown that multiple rRNA operons may confer a competitive advantage during fluctuations in nutrient supply.

Metabolic Engineering

The group of Pronk has recently constructed a xylose-fermenting *S. cerevisiae* strain for alcohol production from the pentose. They inserted a xylose isomerase from a fungus in this yeast, which was originally incapable of metabolizing xylose even under aerobic conditions. The xylose isomerase converts the sugar into xylulose, which can be metabolized by the yeast. Once this was accomplished, oxygen-limited and anaerobic batch enrichment in the presence of high-xylose concentrations led to the selection of mutants that grew faster on xylose and eventually they ended up with a mutant that grew anaerobically on xylose. Genetic engineering to add bottleneck enzymes of the pentose phosphate cycle yielded a mutant that could grow anaerobically on xylose at a rate of 0.09 h^{-1} . The organism showed, however, a strong diauxic behavior towards xylose in the presence of glucose, which was undesirable for application in the commonly available industrial sugar mixtures derived from processing of wood for paper production. Subsequent selection was then performed in an anaerobic chemostat culture under simultaneous limitation by a mixture of glucose and xylose. Progressive decrease of the residual xylose in the culture indicated the appearance of mutants. A strain was obtained with much improved xylose uptake kinetics and rate of metabolism of the pentose in the presence of glucose, even in batch culture. The authors concluded that the bottleneck in this case was primarily caused by uptake of xylose. This again shows how one can take advantage of the strong selective forces existing in nutrient-limited continuous cultures. Further improvement was accomplished by enrichment of mutants in anaerobic sequencing batch culture to select for faster growth. In the end, a mutant was selected with a $\mu_{\max} = 0.22\text{--}0.25 \text{ h}^{-1}$ in a mixture of (10%, w/v) glucose and (2%) xylose, in which sequential but effective-anaerobic consumption of xylose at a rate of 0.9 g per gram biomass per hour occurred.

Practical Aspects Related to Inevitable Presence of Mutants in the Culture

It is important to note that due to the selective forces operating in the chemostat cultures the (chemostat) culture never is a genetically homogenous “pure” culture. This is augmented by the fact that in most cases the mutation only may give a slight advantage in terms of an increased specific growth rate in the order of 0.01 h^{-1} or less. It is easy to calculate, using Eq. (4) that it would take such a mutant 100 days to make up 1% of the culture in a “steady state.” One may therefore say that it is inevitable that a

number of mutants with slight growth rate advantages will be present in the culture, but that they may only become significant after many volume changes. In practice a steady state is reached in 4–5 volume changes (at $D = 0.01 \text{ h}^{-1}$ a volume change takes 100 h). Given the presence of these competitive mutants the maintenance of prolonged steady states it is not advisable in laboratory studies aimed at investigating the wild-type strain. It is advisable to switch dilution rates after each steady state and to start with a fresh culture (using an original new inoculum from stock) after not more than 3–5 consecutive steady states have been investigated. Reproducibility of any particular steady state must be checked with independent cultures.

Other Interactions in Continuous Culture

When we consider competition for single or mixed substrates, we assume that there are no interactions between the organisms other than competition for the growth-limiting substrate. Commensalism was briefly mentioned, and in its “pure” form it is defined as an interaction involving the excretion of a substrate that is used by a second organism, without any further interaction. Examples are the use of fermentation products or products from an electron acceptor, such as nitrite from nitrate or sulfide from sulfate. Some of these may be toxic and in such cases the first organism may need the second to perform optimally. Secondary products such as vitamins or antibiotics may play a crucial role as well. This may lead to stable coexistence if an organism with the highest affinity for the limiting substrate requires the vitamin from an organism with lower affinity. In the case of an antibiotic, the cell density may determine whether or not coexistence is possible.

Mixed cultures of organisms may also be stable if one organism consumes a substrate toxic to the second. In this way, mixtures of aerobic and anaerobic organisms have been studied in oxygen-limited continuous culture. Oxygen is removed by the first organism, before the second can carry out its obligate anaerobic metabolism as has been demonstrated for a mixture of aerobic heterotrophs and sulfate reducers and even methanogens. More complex interactions include the degradation of xenobiotics by consortia of organisms, where one organism initiates the degradation of the compound, but cannot grow on that product. It needs a second organism to metabolize the first product and excrete a second product that can be used by the first. Examples are known in which four or five organisms maintain themselves in continuous culture in a tightly closed interactive network.

Essential Equipment in Continuous Culturing

From the preceding theoretical consideration, it is clear that the only fundamental design requirement of any continuous culture system is that the culture be kept growing by a continuous input of fresh medium that is balanced by the removal of culture fluid at the same rate. It is essential that the culture is “ideally” mixed, because the theory assumes a totally homogeneous system. A great variety of continuous culture systems have been used over the years, with properly evaluated systems ranging in size from just a few milliliters in modified Hungate tubes that were used for radioactive tracer analysis of metabolic fluxes, up to a 1500 m³ industrial system that is used for the nitrification step in wastewater treatment.

For all practical purposes, it is recommended to use a commercially available fermentor of 1–2 L working volume with a potentially high oxygen transfer capacity to ensure good aeration for aerobic cultivation. If the fermentor is built of glass and stainless steel, or from autoclavable oxygen-impermeable polymers, such a system can also be used for anaerobic continuous cultivation.

It is beyond the scope of this article to elaborate on the detailed design of these systems, but a summary of the important general considerations is included because they are important for the construction of most general-purpose research chemostats. Today many very well-designed chemostat systems are commercially available. In Fig. 12, an example of a small bench scale ($\approx 0.5 \text{ L}$ working volume) continuous culture system is shown. Some of its design characteristics are as follows:

1. It can be used for both aerobic and anaerobic cultivation. For aerobic use, silicone seals and tubing are ideal. For anaerobic cultivation, seals and tubing are typically made from neoprene rubber or similarly impermeable materials, into which holes can easily be drilled to fit the desired assortment of tubing and probes.
2. Sterility is easily maintained because the entire unit can be autoclaved and mixing is done with a magnetic coupling between the motor and the stirring shaft, eliminating potential problems associated with the sealing of the stirring shaft through the lid of the chemostat. For simplicity Fig. 12 shows a stirring bar. However, in fermenters with larger working volumes ($\gg 0.5 \text{ L}$) much more elaborate stirrers with shaft and impellers are required to ensure homogeneity.
3. The medium is supplied by means of a peristaltic pump using a durable rubber such as isoprene or neoprene for anaerobic cultivation. Silicone or any other compatible rubber can be used with aerobic cultures. The culture volume is maintained at a constant level by the removal of fluid at the same rate that it enters. In the example, an overflow is shown for simplicity. However, the drawback is that such devices may not remove representative materials from the culture. Therefore the best device is a second pump removing liquid from below the liquid surface and which is activated by a sensor touching the surface of the culture.
4. In some cases, an appropriate low cost and/or simple continuous culture system may be used. It is essential, however, that such a system be designed appropriately for its intended purpose and thoroughly checked for adequate performance. For example, the use of potentially hazardous and/or expensive compounds, such as ¹⁴C- or ¹³C-labeled substrate, may require using very small working volumes. A simple test that is often overlooked in continuous culture studies and that can easily demonstrate whether the culture is actually limited by the expected substrate is to check the relation and the proportionality of $\bar{C}_X$ with C_{Si} at one chosen intermediate D , when it can be expected that $\bar{C}_S \ll C_{Si}$ (Eq. (12)). A very good example is described by Sauer and

Fig. 12 Schematic drawing of a small-scale (500-mL working volume), low-cost glass chemostat. All gases pass through cotton wool filters (not shown) before entering the fermentor. For anaerobic cultivation the N_2 is freed of traces of oxygen by passage over heated copper turnings. *Rs*, reservoir medium; *Mp*, medium supply pump; *Sa*, sampling bottle; *Ac* and *Al*, acid and alkaline titration inlets, respectively; *pH*, autoclavable pH electrode; O_2 , autoclavable polarographic oxygen electrode; *Re*, redox electrode; T_1 and T_2 , temperature sensor and heating element; *Ga*, sampling outlet for head-space gas analysis; *Cf* and *Cp*, constant flow and pressure regulators, respectively, for maintaining a stable (mixed) flow of N_2 and air over and through the culture; *St* and *Sm*, magnetic stirring bar and motor unit, respectively; *Ef*, effluent from the culture.

colleagues, who used 17 mL Hungate tubes as chemostats to study the dependency of intracellular fluxes of metabolite as a function of specific growth rate. The validation concerned aeration sufficiency, and predicted linearity of the specific consumption rate with the dilution rate as well as biomass yield, residual glucose, and acetate as a function of D .

5. Other potential issues of chemostat design may arise from the use of highly volatile compounds in which an open gas phase may not be appropriate. The use of hydrophobic compounds can be problematic as they are often permeable in rubber tubing and rubber seals, and so proper attention toward chemical compatibility is essential. Most general-purpose chemostats are also insufficient for growth under pressure so the continuous cultivation of hyperthermophiles requiring elevated pressure typically must be done in chemostats whose exteriors are made exclusively from stainless steel. Insufficient stirring and aeration can easily become a problem in cultures grown at very high cell densities, especially in combination with high dilution rates. These can also become a problem at low cell densities if the volume of the culture is scaled up too high and these parameters should therefore be carefully considered when setting up any continuous culture system.
6. One detailed comment must be made on the design of the nutrient-medium inlet, which is of critical importance. The inlet must be able to deliver a regular flow of small droplets to the culture vessel (to minimize any effects of discontinuity in the supply of fresh medium) while simultaneously preventing contamination of the nutrient reservoir by the back growth of organisms in the culture vessel. This is typically accomplished by using a device through which medium droplets fall freely and directly into the culture fluid through a relatively wide glass tube that is kept dry on the inside by a continuous flow of sterile gas in the direction of the culture vessel. However if this device is used at low dilution rate and small culture volume, the drop-wise addition will cause dramatic fluctuations of the concentration of the limiting nutrient in the culture. As a result the coupling between catabolism and anabolism may no longer be optimal, which leads in turn to the low yield.

Important Aspects of Continuous Culture

1. Continuous culture in a chemostat enables the reproducible growth of bacteria and other microorganisms. Consequently, the chemostat is an appropriate tool for quantitative (eco)physiological research.
2. Microorganisms can be studied while growing at submaximal rates.
3. The effect of different growth limitations on the metabolism of the cells can be measured reproducibly.
4. The chemostat is also appropriate for studying the competition of microorganisms and mutants for growth-limiting substrates.

5. Continuous cultivation can also be performed under fluctuating environmental conditions.
6. Recent publications show the great value of chemostat cultivation for functional genomic research and for the selection of industrially relevant mutants.
7. The commercial availability of well-designed chemostat equipment greatly facilitates the introduction of continuous cultivation in the laboratory.

Acknowledgments

The author thanks Dr. J.C. Gottschal for permission to use part of his text on the auxostat and the equipment of the previous edition of this article. O.J. Johnson was coauthor of the earlier version of this chapter.

Glossary

Cathodic polarization Consumption of hydrogen accumulated on the surface of metals by microorganisms attached on the surface.

Exopolymers Organic molecules, mostly carbohydrates and proteins, secreted by microorganisms.

Hydrogen embrittlement Permeation of molecular hydrogen into the metal matrix, resulting in crack and structure deformation.

Microbial-induced (influenced) corrosion An electrochemical process catalyzed by microorganisms through formation of electrochemical potential between the cathode and the anode, cathode depolarization, and attack on metals by generated corrosive products.

Defining Statement

Microorganisms are known for their role in the corrosion and passivation of a wide range of metals and alloys through generation and consumption of electron, but the mechanisms, including depolarization of materials, biomineral formation, complexation through exopolymeric materials, H₂ embrittlement, electron shuttling and nanowire, are still not well understood. The best-known model is the involvement of sulfate-reducing bacteria (SRBs) via sulfate reduction and production of H₂S, but further knowledge about the specific genes and enzymes involved is incomplete. Other proposed mechanisms need substantive experimental evidences to confirm the specific biological basis of those processes. Polymeric polymers are used as physical barrier to separate materials from water and microorganisms to achieve corrosion inhibition, but microorganisms are found to destruct the protective coating over long time of exposure. Prevention of microbial influence corrosion (MIC) is a major challenge because microbial biocides and toxic chemicals cannot kill and inhibit them over a long period of applications.

History and Significance

Corrosion is part of the natural processes of decomposition, providing the key driving force for the Earth's dynamic system. Unfortunately, it has a severe economic consequence to our society and this fact has been recognized at a very early stage of research and development. The estimated loss is ~4% of the gross national product (GNP) due to corrosion, of which 70% of the corrosion is by microorganisms in gas transmission pipelines. The American refinery industry loses \$1.4 billion a year from microbial corrosion alone. Microorganisms are the first colonizer on earth and they are ubiquitous. A wide variety of microorganisms are capable of corrosion and degradation, and the causative microorganisms include both aerobic and anaerobic bacteria as well as fungi. Among them, the SRBs have been the long-known microorganisms in a large number of earlier studies on biocorrosion and they are also the culprits for control and elimination in utilities, and oil and gas industries. In addition to SRBs, exopolymer (slime)- and acid-producing microorganisms are also recognized for their active participation in corrosion processes through mechanisms by which metal ions are complexed and released from matrices of materials with functional groups of the not-well-defined exopolymers, resulting in release of metallic species in the solution. Similarly, fungi are involved in the corrosion of aluminum and its alloys by a process in which organic acids of fungal origin attack the underlying material through the acids produced. Fungi are also shown to be the causative organisms in degradation of concrete, stone and polymeric materials that are widely used for structure as well as protective purposes against metal corrosion.

The importance of microorganisms in the corrosion of metallic materials was first reported by Dutch scientist von Wolzogen Kuhr in 1922 when anaerobic SRBs were postulated to contribute to iron corrosion through removal of hydrogen accumulated at the cathodic site on substratum material surfaces. Since then, microbial influenced corrosion (MIC) has been reported for a much wide range of conditions, including oil fields, offshore, pipelines, pulp and paper industries, armaments, nuclear and fossil fuel power plants, chemical manufacturing facilities, wastewater treatment, drinking water distribution system, food industries, and facilities with membrane applications to ship, airplanes, space station and nuclear depositories. The terminology of microbiological

[☆]*Change History:* In addition to making corrections and improving the coherence of the article, text relating to the proposed role of electron shuttling in corrosion has been added.

This article is an update of J.-D. Gu, Corrosion, Microbial, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 259–269.

corrosion has frequently been used interchangeably with microbiological fouling, but the two are not synonymous on scientific basis. MIC is still not clearly defined on a scientific basis as the biochemical mechanisms involving the responsible microorganisms are still not well defined, and ambiguity and misuse are common in the literature.

Microbial processes contributing to corrosion of metals are several. In general, the presence of inorganic deposits and differential concentration cells of oxygen and chloride without microbial participation are important factors determining the corrosion mechanisms and the extent of corrosion. The presence of microflora and fauna on surfaces of materials alters the local environment further, providing conditions for initiation of metal dissolution or passivation of the material surface. Microbial involvement in corrosion of metals is a result of electron or proton movement at the interface between a substratum and the colonizers, in which adhesion on surfaces is a prerequisite for subsequent alteration of material stability through metabolic activity. Microorganisms form complex communities on surfaces of materials, and develop into a complex heterogeneous structure of biofilms under natural conditions (Fig. 1). Such microbial associations on surfaces can be corrosive or passive and are also responsible for destruction or protection of the underlying materials. Specific aerobic microorganisms obtain electrons from metal oxidation and, at the same time, reduce CO_2 for cellular synthesis and growth. Bacteria growing on these surfaces alter the microenvironments, resulting in depolarization and depletion of local oxygen to create concentration cells for electrochemical process to initiate, and also altering the diffusivity of metabolites and nutrients within the 3 dimensional biofilm structures of microorganisms. During growth and building up of the biofilm, the anaerobic microorganisms can establish near the surface of materials where oxygen is depleted so that SRBs produce H_2S , which reacts and corrodes metals. Corrosion is typically mediated by the hydrogenase activity of the SRBs, particularly in the genus *Desulfovibrio*.

A scanning electron micrograph showing a complex biofilm community developed on surfaces of synthetic materials in a polluted river. The sample was dehydrated and critical point-dried before being coated with palladium and gold for viewing under Scanning electron microscope (scale bar, 2 μm).

Microbial Biofilms and Corrosion

Microorganisms are normally associated with physical surfaces in the natural environment. This is especially true for those in aquatic and terrestrial environments of either oligotrophic or eutrophied conditions. Microorganisms adhere to both non-living and living (tissue) surfaces under submerged or moist conditions, in industrial environments exposed to moisture, and enclosed environments of submarine, space station and deep subsurface depositories. Physical surfaces concentrate nutrients under nutrient-poor conditions and the nutrients serve as chemotactically attractants for certain microorganisms. Microbial growth on such surfaces may result in well-defined colonies to further utilize the nutrients available more efficiently from the surfaces. Adhesion of microorganisms onto surfaces of metals alters the electrochemical characteristics of the material by establishing microelectrochemical concentration cells, in which electron flow can be initiated from anode to cathode. The resultant microbial biofilm can lead to cathodic depolarization due to oxygen depletion near the microbial colonies because of microbial activity and diffusion limitation of O_2 in aqueous phase coupling with an increasingly localized acidity around the microbial colonies.

The structure of a biofilm community on any surface is highly heterogeneous in composition and in structure as well as over time and space. The community composition reflects changes in the local environment, nutritional conditions, and selective competition pressure under the specific environments. Nearly a pure culture of *Pseudomonas aeruginosa* can be resulted in the lung of patients suffering from cystic fibrosis. Microbial attachment onto surfaces can have several effects: (1) enhance the initiation of electrochemical process, corrosion, (2) recruit invertebrates for settlement, and (3) passivate metallic surfaces. An understanding of microbial adhesion processes and characteristics of biofilms is essential for better knowledge of initiation and control of corrosion.

Fig. 1 A scanning electron micrograph showing a complex biofilm community developed on surfaces of synthetic materials in a polluted river. The sample was dehydrated and critical point-dried before being coated with palladium and gold for viewing under Scanning electron microscope (scale bar, 2 mm).

Biofilms can affect corrosion by means of any or a combination of the following factors: (1) direct effects on cathodic or anodic processes to affect electron movement between material and the ambient surrounding, (2) changes in surface film resistivity by microbial metabolites and exopolymeric materials, (3) generation of microenvironmental conditions promoting corrosion, including low oxygenation conditions and acidic microenvironments, (4) establishment of concentration cells facilitating electrochemical reaction to take place, and (5) microbial products in the forms of H_2S and other organic acids that promote the aggressive corrosion of underlying metals. Because microorganisms are ubiquitous and biofilms are present in various environments, their influence on materials covers a wide range of temperature, humidity, salinity, acidity, alkalinity, and barometric conditions. In some cases biofilms may also cause ennoblement of metal rather than corrosion, but the underlying biological mechanisms are still poorly understood. Obviously, there is an apparent lack of fundamental scientific information to reveal the basic biological mechanisms at biochemical and physiological levels. In addition, prediction of both corrosion and passivation of materials especially the rate is almost impossible, indicating the lack of large amounts of scientific data and the factors contributing to the phenomena observed under field conditions.

Adhesion of bacteria onto surface is by means of long-range and short-range forces operating between the bacterial cells and the surfaces from a physics point of view. The known Diffuse Double Layer Theory can be used to explain the process involved. At a distance, attractive forces dominate and allow the close movement between a bacterium and the surface. When moving to a critical distance near to the surface, the repulsion forces emerge and become dominant gradually, keeping bacteria away from the surface. Microorganisms form patches of colonies on any kinds of materials, inducing the formation of differential concentration cells on metals. After the initial adhesion by electrostatic attraction or random collision, organisms divide and form 3-dimensional structures of biofilms, which deplete oxygen and release hydrogen ions. Microorganisms have a specific tendency to selective sites for initial attachment and roughness of material surfaces is generally fundamentally important in the early establishment of biofilms. Such physical factor effects can be identified from investigation by using Atomic Force Microscopy, but the lack of a biological basis for such observations is a big obstacle for further substantiation of the results obtained. For example, surface treatment can modify the metal surfaces to be smoother at the microscopic level and attachment of bacteria on these surfaces is negatively correlated to surface smoothness, offering practical applications to achieve biofilm control by the choice of materials. In food processing and pharmaceutical industries, this approach can lead to significant savings from cleaning and disinfection to maintain high quality of products. The adhesion and biofilm forming process may be gene regulated to synthesis of exopolymeric materials to form a complex biofilm community. Under oligotrophic conditions, microorganisms synthesize large quantities of exopolysaccharides, serving as protectants from desiccation and energy reserves. When nutrients are further depleted, the cells can recycle these polymers as a reserved source of carbon and energy for survival.

The existence of biofilms on surfaces as a concept has gained wide acceptance and knowledge of this aspect has been advanced significantly in recent years. A lack of fundamental understanding of adhesion processes prevents us from formulating effective preventive strategies for the effective control of bacterial biofilms or predicting the potential for biofilm development and damage caused. Biomolecules of signaling have been implicated in these processes and significant advances were made in this line of research. Unfortunately, large quantities of biocides and antibiotics are used in industrial and medical areas, but control of biofilms has little success. Selective microorganisms develop mechanisms to resist toxic chemicals and utilize them as a source of carbon and energy. Microorganisms have ability to sense the chemicals in the environment through active movement closer or away from a specific chemical substance called chemotaxis. Selective chemicals can repel marine bacteria under experimental conditions, but the application challenge is to retain these potent chemicals in a formulated coating on surface for slow release over an extended long period of time.

Aerobic Corrosion Processes

Molecular oxygen (O_2) serves as an electron acceptor for microorganisms to achieve maximal energy for growth under aerobic conditions. When molecular oxygen becomes limited, bacteria have other alternative strategies in utilizing other electron acceptors, including NO_3^- , NO_2^- , Fe^{3+} and Mn^{4+} as examples. Since microorganisms living under natural conditions tend to adhere onto surfaces, cells within a biofilm face shortage in oxygen availability. During aerobic corrosion, the area of metal beneath these colonies acts as an anode, while the area further away from the colonies, where oxygen concentrations are relatively higher, serves as a cathodic site (Fig. 2). Electrons flow from anode to cathode and the corrosion process is initiated. Electrolytes affect the distance between the anode and cathode, being shorter at low and longer at high salt concentrations. An electrochemical potential is eventually developed across the two sites and corrosion reactions take place, resulting in the dissolution of metals. Dissociated metal ions can form ferrous hydroxides, ferric hydroxide, and a series of Fe-containing minerals in the solution phase for iron, depending on the species of microorganisms present and the chemical conditions. Electron flow via oxidation and reduction is fundamental and must occur to consume electrons produced for corrosion to proceed. However, the electrochemical reactions never proceed at theoretical rates because the rate of oxygen supply to cathodes and removal of products from the anodes limit the overall reaction. In addition, impurities and contaminants of the metal matrices also stimulate corrosion by initiating the formation of differential cells and accelerated electrochemical reactions.

When aerobic corrosion occurs, corrosion products usually form a structure consisting of three layers called tubercles (Fig. 3). The inner green layer is mostly ferrous hydroxide $Fe(OH)_2$. The outer one consists of orange ferric hydroxide $Fe(OH)_3$. In between

Fig. 2 A schematic diagram of a differential aeration cell created by biofilm under aerobic conditions on a metal surface leading to corrosion of metal.

Fig. 3 A schematic diagram of a tubercle formed under pitting corrosion condition of metals.

these two, magnetite Fe_3O_4 forms a black layer. The most aggressive form of corrosion is tuberculation caused by the formation of differential oxygen concentration cells on metal surfaces. The overall reactions are expressed as follows:

Initial oxidation of Fe of mild steel at near-neutral pH is driven by dissolved O_2 . Subsequent oxidation of Fe^{2+} to Fe^{3+} is an energy-producing process carried out by a few specialized species of microorganisms autotrophically. The amount of free energy gained from this reaction is small, approximately -31 kJ , so large quantities of Fe^{2+} are oxidized to support microbial growth. This is especially true in an intertidal environment where alternation of oxic and anoxic conditions is facilitated by tidal activity. Because the Fe^{2+} oxidative reaction is rapid under natural conditions, microorganisms compete with chemical processes for Fe^{2+} . As a result, biological involvement under aerobic conditions may be underestimated.

A number of aerobic microorganisms play an important role in corrosion, including the sulfur bacteria, iron- and manganese-depositing and slime-producing bacteria, fungi, and algae. At neutral pH, Fe^{2+} is not stable in the presence of O_2 and is rapidly oxidized to the insoluble Fe^{3+} state. In fully aerated freshwater at pH 7, the half-life of Fe^{2+} oxidation is less than 15 min. Because of this, the only neutral pH environments where Fe^{2+} is present are interfaces between anoxic and oxic conditions. Improved culturing techniques allowed the isolation of new Fe^{2+} -oxidizing bacteria under microaerophilic conditions at neutral pH. Ferric oxides may be enzymatically deposited by *Gallionella ferruginea* and non-enzymatically by *Leptothrix* sp., *Siderocapsa*, *Naumanniella*, *Ochrobium*,

Siderococcus, *Pedomicrobium*, *Herpetosyphon*, *Seliberia*, *Toxothrix*, *Acinetobacter*, and *Archangium*. Questions remain as to the extent of microbial involvement in specific processes of corrosion involving iron oxidation.

Other microorganisms in the genus of *Thiobacillus* are also responsible for oxidative corrosion. Because they oxidize sulfur compounds to sulfuric acid metabolically, the acid around the cells may attack metals and alloys as well as stone and concrete. *Thiobacillus* is the most common and *Thiobacillus ferrooxidans* oxidizes Fe^{2+} to Fe^{3+} , but the product limits growth of the organisms. SO_4^{2-} is required by the Fe-oxidizing system in *T. ferrooxidans* at the surface of the bacteria. The electrons removed from Fe^{2+} are passed onto periplasmic cytochrome *c*. The reduced cytochrome *c* binds to the outer plasmic membrane of the cell, allowing transport of electrons across the membrane to cytochrome oxidase located in the inner membrane. Recent findings also emphasize the importance of bacterial physiology and water chemistry as the most important determinants of microbial corrosion through generation of mutants defect of biofilm formation and measurement of electrochemical impedance spectroscopy (EIS).

Most microorganisms accumulate Fe^{3+} on their outer surface by reacting with acidic polymeric materials. Such mechanisms have important implications not only for corrosion of metals, but also for the accumulation of metals under natural conditions. *Aquaspirillum magnetotacticum* is capable of taking up complexed Fe^{3+} and transforms it into magnetite Fe_3O_4 by reduction and partial oxidation. The magnetite crystals are single-domain magnets and they play an important role in bacterial orientation to the two magnetic poles of the earth in natural environments. However, some non-magnetotactic bacteria can also form extracellular magnetites. The role of these bacteria has been articulated in carbon cycling in natural ecosystem but their role in metal corrosion is still not known. Recent studies indicated that microorganisms may also contribute to corrosion through electron shuttling process, but such mechanism must be confirmed to realize their importance and significance in the corrosion of metals.

Anaerobic Corrosion Processes

Oxygen is a relatively new invention by microorganisms and has altered the evolution history on Earth. Anaerobic microorganisms were the early colonizers and then survive the increasing concentration of oxygen by living in oxygen limited sediment and intestinal tracts of animals. The gelatinous matrix of a heterogeneous biofilm contains both oxic and anoxic zones, permitting both aerobic and anaerobic processes to take place simultaneously. In the absence of oxygen, anaerobic bacteria, including methanogens, SRBs, and acetogens, may actively participate in corrosion processes. Emphasis has traditionally been on SRBs and hydrogenases, in which the hydrogen on metal surfaces is consumed by microbial metabolism. Severe damage of metals by SRBs is common in oilfields and sewage systems. However, the involvement of SRBs and their hydrogenases in corrosion of mild steel is still controversial.

SRBs are among the most intensely investigated groups of microorganisms on their role in biological corrosion. Under anaerobic conditions, oxygen is not available to accept electrons produced. Instead, SO_4^{2-} or other compounds are used as electron acceptors under such conditions. Each type of electron acceptor is unique in the pathway of metabolism. When corrosion begins, the following reactions take place:

von Wolzogen Kuhr and van der Vlugt suggested that the above set of reactions is caused by SRBs. This electrochemical generalization has been accepted and is still prevalent. During corrosion, the redox potential of the bacterial growth medium is -52 mV. After inoculation of SRBs into a corrosion testing cell, the overall internal resistance decreases from the initial value of 15 Ohms to approximately 1 Ohm, while the sterile cell actually shows an increase in resistance. Several phases of change in the electrical potential of steel can be observed after inoculation with SRBs. Before inoculation, the value is determined by the concentrations of hydrogen ions in the medium. A film of hydrogen molecules forms on surfaces of Fe and steel, inducing polarization. Immediately after inoculation, SRBs begin to grow to cause depolarization, resulting in a drop of 50 mV in the anodic direction. The SRBs by means of their hydrogenase system remove the adsorbed hydrogen, depolarizing the system. The overall process was described as depolarization, based on the theory that these bacteria remove hydrogen that accumulates on the surface of metals and alloys. The electron removal as a result of hydrogen utilization results in cathodic depolarization and forces more iron to be dissolved at the anode. A typical polarization curve is shown in Fig. 4 where both current density and polarization potential of the metal specimen are shown.

Fig. 4 A polarization curve showing the relationship between corrosion potential and current density during corrosion of metals.

Since direct removal of hydrogen from the surface is equivalent to lowering the activation energy for hydrogen removal by providing a depolarization reaction, the hydrogenase enzyme in many species of *Desulfovibrio* spp. is believed to be involved in this specific depolarization process. Under anaerobic conditions, particularly in the presence of SRB, SO_4^{2-} in the aqueous phase can be reduced to S^{2-} microbiologically. The biogenically produced S^{2-} reacts with released Fe^{2+} to form precipitate of FeS on metal surfaces. Controversy surrounding the mechanisms of corrosion includes more complex mechanisms involving both sulfide and phosphide, and processes related to hydrogenase activity. The addition of chemically prepared Fe_2S and fumarate as electron acceptors also depolarizes. However, higher rates are always observed in the presence of SRBs. As a result of the electrochemical reactions, the cathode always tends to be alkaline with an excess of OH^- . These hydroxyl groups also react with ferrous irons to form precipitates of hydroxy iron. Precipitated iron sulfites are frequently transformed into minerals, such as mackinawite, greigite, pyrrhotite, marcasite, and pyrite. Biogenic iron sulfides are identical to those produced by purely inorganic processes under identical conditions.

SRBs are divided into two physiological groups: one group utilizes lactate, pyruvate, or ethanol as carbon and energy sources, reducing sulfate to sulfide. Examples are *Desulfovibrio*, *Desulfomonas*, *Desulfotomaculum*, and *Desulfobulbus*. The other group oxidizes fatty acids, particularly acetate, reducing sulfate to sulfide. This group includes *Desulfobacter*, *Desulfococcus*, *Desulfosarcina*, and *Desulfonema*. Some species of *Desulfovibrio* lack hydrogenase. For example, *Desulfovibrio desulfuricans* is hydrogenase negative and *Desulfovibrio salexigens* is positive. The rate of corrosion by these bacteria is correlated with their hydrogenase activity. Hydrogenase-negative SRBs were completely inactive in corrosion. Apparently, hydrogenase-positive organisms utilize cathodic hydrogen depolarizing the cathodic reaction, which controls the kinetics of corrosion. In contrast to this theory, ferrous sulfide FeS is suggested to be the primary catalyst for initiation of corrosion.

Corrosion by SRBs is mediated by the hydrogenase enzyme system. Available information suggests that a protective film of atomic hydrogen is formed on the surface of metals and this neutralizes any further electrochemical reaction, for example, initial exposure of metal to soil and water. However, SRBs disrupt this delicate balance by utilizing this hydrogen as an energy source, resulting in further oxidation of iron or metals to maintain the initial electrochemical steady state. In this process, biochemically, an iron hydrogenase takes an electron from the steel surface and the enzyme is thought to be located on the exterior surface of the outer membrane in order to utilize the surface-adsorbed hydrogen on metals. Hydrogenases have been found only in the periplasm, cytoplasmic membrane, and cytoplasm of the SRBs. *Desulfovibrio vulgaris* contains three hydrogenases, Fe, NiFe, and NiFeSe, in various quantities and in specific locations of the cells. Approximately 95% of the hydrogenase activity is found to be associated with periplasmic Fe hydrogenases and the remaining with cytoplasmic membrane-bound NiFe hydrogenase and a very small fraction by the NiFeSe cytoplasmic hydrogenase. To explain this, Fe^{2+} regulation may play an important role in controlling the synthesis of key proteins associated with out-membrane and periplasm for hydrogen generation. The depolarization theory suggests that bacteria, for example, SRBs, utilize the protective hydrogen layer on metal surfaces through the hydrogenase. This requires the hydrogenase to be localized on the outer membrane's exterior surface to access and utilize the hydrogen. Since only a very small fraction, that is, 1%, of periplasmic Fe hydrogenase activity is associated with the out-membrane, high molecular weight cytochrome in the out-membrane may be the initial electron transporter for hydrogen to be passed onto Fe hydrogenase, which is located next to the cytochrome but inward.

Other microorganisms should be noted for their potential role in anaerobic corrosion. They include methanogens, acetogens, thermophilic bacteria, archaea and obligate proton reducers. Among them, only methanogens have been implicated for their role in corrosion of metals. As all microorganisms have metabolic capability in utilizing hydrogen, it would not be a big surprise to confirm their role in corrosion of metals. More research work is needed to elucidate the role of these organisms in corrosion to further enrich our understanding of this subject.

Alternating Aerobic and Anaerobic Conditions

Corrosion under natural conditions may not be constantly anoxic or anaerobic over time, and most of the time alternation of aerobic and anaerobic conditions may take place. In this case, corrosion can be accelerated greatly when transformation of elemental sulfur is considered as sulfate is reduced to H_2S by SRBs under anaerobic conditions, but H_2S is oxidized to elemental S^0 and sulfate and other S species, which generates acidity. Acid attack is a significant process contributing to the corrosion of metals and also inorganic materials including stone and concrete. Since elemental S can be recycled further, such process is carried out continuously, resulting in dissolution of metals and significant deterioration of inorganic materials. Since constant oxic or anoxic conditions are rare in natural or industrial environments, alternating of the two conditions, depending on oxygen gradient and diffusivity in a specific environment and microbial activity, is common. Microbial corrosion under such conditions is quite complex, involving two generally different groups of microorganisms; an interface that serves as a transitional boundary of the two conditions can also be established. Such system is complicated for scientific investigation, and a recognized and generally agreed model system should be used for such research to obtain information on the relative contribution of each group of microorganisms. Resultant corrosion rates are often higher than those observed under either continuous oxic or anoxic conditions. Microbial activity reduces the oxygen level at the oxic–anoxic interface, facilitating anaerobic metabolism when nutrients are available. The corrosion products resulting from anaerobic processes, such as FeS, FeS_2 , and SO, can be oxidized when free oxygen is available.

Stainless steel is more resistant to corrosion than mild steel because of the formation of a passivation film on the metal surfaces. Pitting corrosion of stainless steel is often initiated, in particular, in areas of welding and crevices or impurity as commonly observed in applications. Corrosion of stainless steel AISI 304 and AISI 316 is often associated with marine environments. During oxidation of reduced sulfur compounds more corrosive sulfides are produced under anoxic conditions through microbial physiological processes, causing cathodic reactions. The corrosion rate increases as the reduced and oxidized FeS concentrations increase. Corrosion rate of iron by H_2S is accelerated through formation of FeS, which decreases hydrogen concentration at the cathode site of the metal surface. In such a system, metal serves as an anode. During corrosion of iron and steel by SRB, a thin layer of $\sim 1\ \mu\text{m}$ thickness is always observed as an adherent layer of tarnish and has been confirmed to be mackinawite (tetragonal FeS_{1-x}). This layer becomes loosen when it grows. When Fe^{2+} concentration is low, the mackinawite changes to greigite. This transformation of minerals is only observed when microorganisms are involved. If Fe^{2+} concentration is high, mackinawite is accompanied by green rust, which is a ferrosferric oxyhydroxide. Mackinawite under condition of SRB can be further transformed to greigite Fe_3O_4 , smythite Fe_9S_{11} , and finally to pyrrhotite FeS_{1+x} . Formation of these minerals also accelerates the equilibrium established between soluble fraction and metals.

Corrosion Via Microbial Exopolymeric Products

Bacteria are known to produce copious quantities of exopolymers, which are important because of their pathogenicity and survival in natural and artificial environments. Such organic materials, in addition to their ecosystem function in recruitment of larvae in aquatic environment and formation of mutualistic or pathogenic relationship with plants and animals, appear to be implicated in their role in corrosion process. These exopolymers consisting mostly of polysaccharides and proteins are acidic and contain reactive functional groups that bind metal ions tightly. These exopolymers play an important role in facilitating the adhesion of bacterial cells onto surfaces during their initial natural development. These materials have been found to be involved in severe corrosion of copper pipes of water supplies in buildings and hospitals after water stagnation for a period of time. Using surface analysis employing XPS, the organic fraction of the chemicals influences the electrochemical characteristics of metals through functionality-rich materials to complex metal ions from the surface of metal matrix, releasing them into aqueous solution in soluble and complexed forms. As a result, corrosion is initiated. Proteins in bacterial exopolymeric materials use their disulfide-rich bonds to induce corrosion very effectively through chemical reaction. Current understanding on the chemical constituents in the exopolymeric materials of any bacteria is still very rudimentary as the analysis has been on several different categories of chemicals, for example, polysaccharides, proteins, uronic acid, 2-keto-3-deoxyoctanoic acid, and deoxyribonucleic acid. Other chemicals, especially those at low concentration but significant role to corrosion, must be identified and evaluated.

Purified exopolymeric materials of *Deleya* (*Pseudomonas*) *marina* were used in an investigation. Proteins in the exopolymeric materials are responsible for reduction of molybdate MoO_4^{2-} under deaerated conditions through comparison with the same exopolymeric materials where proteins have been removed. The reduction process is thought to be due to the presence of proteins containing disulfide moieties. The resultant Mo^{5+} species can be reoxidized when molecular oxygen is available in the ambient environment. Such reduction process can also be observed on the surface of the MoO_4^{2-} -treated austenitic type 304 SS and formation of MoO_2 was detected. Though exposure to the exopolymer results in surface depletion of Fe and enrichment of Cr, rendering an increased hydration of Cr, corrosion resistance of the SS is not compromised by the exopolymer attachment on the surface. Since the duration of the experiment was short and the chemicals were purified, such factors must be taken into account when considering long-term exposure and life-span assessment. On the other hand, aluminum is very susceptible to corrosion by fungi and results have shown that fungal hyphae formed imprints into the aluminum alloys through acids produced during fungal metabolism. It is clear here that microorganisms play at least two roles in inducing corrosion, one by the exopolymeric materials synthesized and the other by direct attack through the acidic products released.

In addition to their genetic basis, production of bacterial exopolymers is affected by several environmental factors. Polysaccharide production by *Enterobacter aerogenes* is stimulated by the presence of Mg^{2+} , K^+ , and Ca^{2+} ions in the culture media. Toxic metal ions, for example, Cr^{6+} , can also enhance the synthesis of polysaccharides and other exopolymeric materials in selective bacteria as a response to the chemical in the culture medium. In particular, synthesis of the exopolymeric materials is positively correlated with Cr^{6+} concentration in *Vogesella indigofera*. Specific chemical molecules involved in corrosion process need to be identified and the corrosion mechanisms by them shall be postulated and confirmed to further advance our understanding on the science of corrosion and then the controlling strategies against corrosion in various applications.

Microbial Hydrogen Embrittlement

Biologically produced hydrogen (H_2) has been more widely known in energy-related research and development in recent years. This process of release of hydrogen ion or molecular hydrogen by microorganisms is a common phenomenon associated with many different groups of microorganisms. However, the role of bacteria in embrittlement of metallic materials is not fully understood and the limited number of publications only postulates the potential importance of such biological process on material integrity. During the growth of bacteria, fermentation processes convert complex organic compounds to simpler organic acids and molecular hydrogen H_2 . Such hydrogen, when generated and released on the surface of materials, can be absorbed into material matrix, causing polarization. Some bacteria, particularly the methanogens, sulfidogens, and acetogens, are also capable of hydrogen utilization.

Initially, a possible role for microbial hydrogen in hydrogen embrittlement of metal was proposed. Permeation of microbial hydrogen into metal was measured using a modified Devanathan cell with a mixed microbial community commonly found in nature, hydrogen production and consumption occur simultaneously. In the complex natural system, competition for hydrogen between microbial species determines the ability of hydrogen to permeate into metal matrices, causing crack initiation. In a pure culture of *Clostridium acetobutylicum* ATCC 824, hydrogen produced by bacteria can be absorbed by palladium foil was demonstrated through monitoring of current density during bacterial growth. Microbial hydrogen involved in material failure may be explained by two distinctively different hypotheses: pressure and surface energy changes. The kinetic nature of hydrogen embrittlement of cathodically charged mild steel is determined by the competition between diffusion and plasticity. The strength level and the susceptibility of the alloy are positively correlated. However, microstructures were also proposed to be the more critical determinant of material susceptibility. Hydrogen permeation increases the mobility of screw dislocations, but not the mobility of edge dislocations.

Corrosion by Other Microbial Metabolites

The microbial world is complex and majority of them are too small to be observed visually. Bacteria have a complex metabolic network to produce a diverse group of chemicals as their degradation intermediates. Some of the chemicals can accumulate and may be corrosive depending on the metabolic process. Fermentative microorganisms thriving under reduced availability of oxygen and in the presence of sufficient carbon source can produce simple organic acids, formic, acetic, butyric, and so on. In addition to these physiological and biochemical capabilities, microorganisms are also of producing extracellular electron shuttling molecules, which may have a significant role in the corrosion of metals.

Fungi produce highly corrosive metabolites including a wide range of organic acids, which corrode fuel tanks. They survive very well at the water–fuel interface and aqueous phase, metabolizing the fuel hydrocarbon as carbon and energy sources. Fungi are also capable of generating corrosive oxidants, including hydrogen peroxide. Degradation of protective coating is an issue because the underlying metals are dependent on the integrity of the polymer for corrosion control. Fungi cause deterioration of a wide array of polymeric materials, including electronic polyimides, packaging cellulose acetate, epoxy resins, and protective coatings.

Electron Shuttling in Corrosion

Electron transfer is the most fundamental and basic electrochemical process in the corrosion of metallic materials regardless of the participation of microorganisms. Such electron transfer process is facilitated by natural molecules, for example, humic substances, commonly found in the environment, both aquatic and terrestrial. More recently, results showed that bacterial quinone, an effective electron transferring molecule, can be excreted by the bacterium *Shewanella putrefaciens*, suggesting that extracellular process of electron transport may initiate and participate actively in the corrosion of metals. It would be interesting to further investigate the extent of such microbial electron transport process in corrosion and the mechanisms involved using candidate electron transfer chemical molecule.

Direct contact between bacterial cells and the metal oxide is required for the energy conservation process and such system may provide further insights in understanding the mechanisms involved in metal corrosion. For example, enzymatic reduction of $Cr(VI)$ has been observed in a number of bacteria and the reduction of $Cr(VI)$ is achieved by either soluble enzyme systems or the membrane-bound system. Membrane-associated chromate reductase activity was first observed in *Enterobacter cloacae* HO1 where

the insoluble form of reduced chromate precipitates was detected on the cell surfaces. In the presence of ascorbate reduced phenazine methosulfate (PMS) as electron donor, active chromate reduction has been shown in membrane vesicles of *E. cloacae* HO1. Membrane-associated constitutive enzyme that mediated the transfer of electrons from NADH to chromate was later elucidated. In the case of *Sh. putrefaciens* MR-1 chromate reductase activity is associated with the cytoplasmic membrane of anaerobically grown cells. Formate and NADH serve as electron donors for the reductase. No activity is observed when NADPH or L-lactate is provided as the electron donor. However, in *Pseudomonas putida*, unlike in *Sh. putrefaciens*, NADPH serves as an electron donor. The presence of soluble chromate reductase is possible in *Escherichia coli*. Cr(VI) reduction in another Gram-negative bacterium, *Pseudomonas* species CRB5, was mediated by a soluble enzyme in cytoplasm. In addition to Gram-negative bacteria, soluble chromate reductases have also been observed in Gram-positive strains. NADH is the preferred electron donor for the reduction of chromate by the soluble enzyme in *Bacillus coagulans*.

Enzymes capable of Cr(VI) reduction are often referred to as 'chromate reductases' in the literature. Several bacterial Cr(VI) reductases, some conferring resistance to chromate, have been characterized. These enzymes commonly show a NADH:flavin oxidoreductase activity and use Cr(VI) as electron acceptor. The ability to reduce chromate may be a secondary function for Cr(VI) reductases, which have a primary role other than Cr(VI) reduction. This is likely true as the gene sequences available from GenBank indicate that the *P. putida* chromate reductase is a quinone reductase (AF375641) that has a bound flavin and *Pyrus ambigua* ChrR is a flavin reductase (D83142). The nitroreductases NfsA/NfsB from *Vibrio harveyi* possess a nitrofurazone nitroreductase as primary activity and a Cr(VI) reductase activity as a secondary function. Similarly, ferric reductase FerB from *Paracoccus denitrificans* uses both Fe(III)-nitrotriacetate and Cr(VI) as substrates. These secondary functions may be related to the bacterial enzymatic adaptation as a result of the relatively recent increase of Cr(VI) in the environment due to anthropogenic activities.

YieF is a flavoprotein containing the FMN cofactor and the enzyme is able to reduce chromate in vitro. YieF possesses quinone reductase activity, which appears to guard against oxidative stress by preventing redox cycling of quinones, which would otherwise generate ROS, and by maintaining a pool of reduced quinone in the cell that is able to quench ROS directly. The quinone reductase activity of YieF is likely the primary biological role of this enzyme. ChrR of *P. putida* is the currently best-studied Cr(VI) reductase. During Cr(VI) reduction, ChrR shows a quinone reductase activity that generates a flavin semiquinone. Cr(VI) is reduced to Cr(V) by ChrR, previously reduced by NADH; Cr(V) is next converted to Cr(III) by diverse biomolecules generating reactive oxygen species (ROS). ROS may be eliminated by alternative mechanisms (i.e., catalases or peroxidases) or by the additional function of ChrR. ChrR in a reduced status may reduce quinines (such as Vitamin K or Coenzyme Q), which may then detoxify previously formed ROS. The soluble bacterial quinone reductase has the ability to reduce a variety of quinone substrates. The above model may provide a unique system for verification of electron shuttling in corrosion of metals.

Prevention and Control

A common practice to eradicate the initiation and development of microbial biofilm on the surfaces of a wide range of materials in engineering systems of industries is through introduction of biocides. Chlorination and glutaldehyde are routinely used as a preventive measure in water cooling system and oil fields. Chlorination yields secondary halogenated by-products, resulting in environmentally unacceptable residues of chemicals. In addition, biofilm bacteria are distinctively different from the planktonic ones in their resistance to toxic chemicals and environmental shock. In addition, biocidal effect is compromised with biofilm formed on surfaces of materials. However, this has not been taken into account for testing the effectiveness of biocides in different industries against biofilm bacteria.

Biofilm structures are advantageous for the microorganisms because diffusion is limited to prevent penetration of disinfectants and to facilitate more effective exchange of genetic materials between members. Organic biocides, used to prevent bacterial growth in industrial systems for an extended period of time, enrich a population capable of biocide resistance by genetic modification in bacteria, for example, by recruitment of extracellular DNA. However, a new generation of environmentally acceptable biocides is also available, and their application and effectiveness have to be tested over time to provide further information on effectiveness. It is probable that some of these biocides are capable of either preventing biofilm formation or killing the microorganisms in formed biofilms, but it is unrealistic to expect a magic biocide for eradicating microbial biofilms over a long period of time.

Corrosion protective coatings also have wide applications because of the development of metallic materials and susceptibility to both environmental and microbiological corrosion. Polymeric coatings are designed to prevent contact of the underlying materials with corrosive media and microorganisms. However, microbial degradation of coatings may accelerate and severely damage the underlying metals. A typical example is the corrosion of underground storage tanks and oil tanks of airplanes and ship. Natural populations of bacteria form microbial biofilms on surfaces of coating materials, including epoxy and polyamide primers and aliphatic polyurethanes. Surprisingly, the addition of biocide diiodomethyl-*p*-tolylsulfone in polyurethane coatings did not inhibit bacterial attachment or growth effectively due to development of biofilm and bacterial resistance.

Metal protective coatings are physical barrier separating metal surface from water and microorganisms so that corrosion can be inhibited. Polyurethane coating is commonly used and polyurethane-degrading microorganisms including *Fusarium solani*, *Curvularia senegalensis*, *Aureobasidium pullulans*, and *Cladosporidium* sp. through esterase activity detected with *C. senegalensis* are also known. A number of bacteria, including four strains of *Acinetobacter calcoaceticus*, *Arthrobacter globiformis*, *Pseudomonas aeruginosa*, *Pseudomonas cepacia*, *P. putida*, and two other *Pseudomonas*-like species, are capable of degrading polyurethane. In addition, *Pseudomonas chlororaphis* encodes a lipase responsible for degradation. Using EIS, both primers and aliphatic polyurethane coatings

were shown for their biodegradation by bacteria and fungi, indicating that primers are more susceptible to degradation than polyurethane top coating. The degradation process is similar to mechanisms as shown for electronic insulation polyimides. Aliphatic polyurethane-degrading bacteria can be isolated and one of them is *Rhodococcus globerulus* P1 base on a 16S rRNA sequence.

Microbial growth and propagation on material surfaces can be controlled efficiently by physical and chemical manipulations of the material types and the artificial environments. Surface engineering so to prevent the attachment by and susceptibility to microorganisms can be used to limit occurrence of biodeterioration. As a control measure, lowering humidity is a very effective means to slow down the growth of microorganisms on surfaces in an enclosed environment and prevention against potential contamination can extend the life time of the materials.

Biocides are commonly applied in repairing, cleaning, and maintenance of artworks. Chlorine, iodine, and other organic biocidal compounds are used widely and routinely in controlling biofilms that cause corrosion and deterioration of a wide range of materials in industries and for conservation of art. These chemicals have been shown to be ineffective in killing biofilm bacteria. In addition to their environmental unacceptability, most of the time because of toxicity, biocides induce the development of biofilms that are highly resistant to the levels of chlorine normally utilized to prevent biocorrosion. Organic biocides, used to prevent bacterial growth in industrial systems, may selectively enrich populations of microorganisms capable of biocide resistance. No solution to these problems is currently available and alternative biocides have been screened from natural products. Current research by materials scientists focuses on the prevention of adhesion of corrosive microorganisms to surfaces through surface treatments and modification.

Since bacteria are capable of forming biofilms on surfaces of materials, future tests should focus on the dynamics of biofilm and quantification than descriptively show biofilms of scanning electron micrographs. In particular, tests for assaying efficacy of biocides should be conducted based on biofilm condition than for liquid culture efficacy. This major discrepancy has not been resolved fully. Because biofilm bacteria are more resistant to antibiotics and biocides, tests based on planktonic cells are not truly representative of their actual conditions on surfaces of materials. New initiative is needed for innovative methodology to assess biocidal effects and mechanisms using surface-oriented assays similar to the application conditions.

Conclusions

Under both aerobic and anaerobic conditions, microorganisms can directly or indirectly participate in the electrochemical process of metal corrosion. Under anaerobic conditions bacteria corrode metals by cathodic depolarization and the formation of FeS, or by consuming hydrogen produced by polarization. Other corrosion mechanisms, including microbial hydrogen embrittlement, complexation of metals from matrices by microbial exopolymeric materials, or extracellular electron respiration, have also been implicated in recent years. It is clear that a better understanding of the complexity of interactions between microflora and metals leading to corrosion can be facilitated by the elucidation of specific mechanisms involved. Molecular biology-based investigation coupled with electrochemistry and chemical biology should permit a better knowledge of the fundamental biochemical processes, genes and the role of microorganisms in corrosion of metals. Equipped with basic knowledge, it is feasible to formulate strategies for controlling biofilms and MIC in industrial and other environments. Use of biocides cannot solve the MIC problems, but spreading of antibiotic-resistant microorganisms is a much more serious to be addressed by the professionals and also the general public.
